GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is arranged as a series of articles in alphabetical order.

There are four features to help you easily find the topic you're interested in: an alphabetical contents list, cross-references to other relevant articles within each article, and a full subject index.

1 Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

2 Cross-References

Most of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an entry as a See also list, serve four different functions:

i. To draw the reader's attention to related material in other entries.
ii. To indicate material that broadens and extends the scope of the article.
iii. To indicate material that covers a topic in more depth.
iv. To direct readers to other articles by the same author(s).

Example

The following list of cross-references appears at the end of the entry Critical Tracking Events Approach to Food Traceability.

> *See also*: Agribusiness Organization and Management. Food Chain: Farm to Market. Food Labeling. Food Law. Food Packaging. Food Security: Development Strategies. Food Security: Food Defense and Biosecurity. Food Security, Market Processes, and the Role of Government Policy. Food Security: Postharvest Losses. Global Food Supply Chains. Government Agricultural Policy, United States. Regulatory Conventions and Institutions that Govern Global Agricultural Trade

3 Index

The index includes page numbers for quick reference to the information you're looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4 Contributors

At the start of each volume there is list of the authors who contributed to that volume.

SUBJECT CLASSIFICATION

Agriculture and People

Agribusiness Organization and Management
Agricultural Cooperatives
Agricultural Ethics and Social Justice
Agricultural Finance
Agricultural Labor: Demand for Labor
Agricultural Labor: Gender Issues
Agricultural Labor: Labor Market Operation
Agricultural Labor: Supply of Labor
Agricultural Law
Agricultural Policy: A Global View
Analyses of Total Phenolics, Total Flavonoids, and Total Antioxidant Activities in Foods and Dietary Supplements
Changing Structure and Organization of US Agriculture
Climate Change, Society, and Agriculture: An Economic and Policy Perspective
Computer Modeling: Policy Analysis and Simulation
Consumer-Oriented New Product Development
Crop Insurance
Determining Functional Properties and Sources of Recently Identified Bioactive Food Components: Oligosaccharides, Glycolipids, Glycoproteins, and Peptides
Farm Management
Food Chain: Farm to Market
Food Labeling
Food Law
Food Marketing
Food Security, Market Processes, and the Role of Government Policy
Food Security: Development Strategies
Food Security: Food Defense and Biosecurity
From Foraging to Agriculture
Global Food Supply Chains
Government Agricultural Policy, United States
Human Nutrition: Malnutrition and Diet
Industrialized Farming and Its Relationship to Community Well-Being
Intellectual Property in Agriculture
International and Regional Institutions and Instruments for Agricultural Policy, Research, and Development
International Trade
Investments in and the Economic Returns to Agricultural and Food R&D Worldwide
Markets and Prices
Mathematical Models to Elaborate Plans for Adaptation of Rural Communities to Climate Change
Policy Frameworks for International Agricultural and Rural Development
Production Economics
Quantitative Methods in Agricultural Economics
Regulatory Conventions and Institutions that Govern Global Agricultural Trade
Rural Sociology
Safety of Street Food: Indonesia's Experience
Social Justice: Preservation of Cultures in Traditional Agriculture
Vitamins and Food-Derived Biofactors

Agriculture and the Environment

Agroforestry: Conservation Trees and Erosion Prevention
Agroforestry: Hydrological Impacts
Air: Confined Animal Facilities and Air Quality Issues
Air: Greenhouse Gases from Agriculture
Biodiversity and Ecosystem Services in Agroecosystems
Biodiversity: Conserving Biodiversity in Agroecosystems
Climate Change: Agricultural Mitigation
Computer Modeling: Applications to Environment and Food Security
Crop Pollination
Dust Pollution from Agriculture
Ecoagriculture: Integrated Landscape Management for People, Food, and Nature
Economics of Natural Resources and Environment in Agriculture
Energy and Greenhouse Gases Footprint of Food Processing
Land Use: Catchment Management
Land Use, Land Cover, and Food-Energy-Environment Trade-Off: Key Issues and Insights for Millennium Development Goals
Land Use: Management for Biodiversity and Conservation
Land Use: Restoration and Rehabilitation
Linkages of the Agricultural Sector: Models and Precautions
Market-Based Incentives for the Conservation of Ecosystem Services in Agricultural Landscapes: Examples from Coffee Cultivation in Latin America
Natural Capital, Ecological Infrastructure, and Ecosystem Services in Agroecosystems

Soil: Carbon Sequestration in Agricultural Systems
Soil: Conservation Practices
Soil Greenhouse Gas Emissions and Their Mitigation
Soil: Nutrient Cycling
Virtual Water and Water Footprint of Food Production and Processing
Water: Advanced Irrigation Technologies
Water Use: Recycling and Desalination for Agriculture
Water: Water Quality and Challenges from Agriculture
Weather Forecasting Applications in Agriculture
World Water Supply and Use: Challenges for the Future

Agriculture Products

Advances in Pesticide Risk Reduction
Agricultural Mechanization
Agroforestry: Complex Multistrata Agriculture
Agroforestry: Fertilizer Trees
Agroforestry: Fodder Trees
Agroforestry: Participatory Domestication of Trees
Agroforestry: Practices and Systems
Asian Aquaculture
Beef Cattle
Climate Change: Animal Systems
Climate Change: Cropping System Changes and Adaptations
Climate Change: Horticulture
Climate Change: New Breeding Pressures and Goals
Critical Tracking Events Approach to Food Traceability
Dairy Animals
Edaphic Soil Science, Introduction to
Fermentation: Food Products
Fermented Beverages
Food Engineering
Food Microbiology
Food Packaging
Food Safety: Emerging Pathogens
Food Safety: Food Analysis Technologies/Techniques
Food Safety: Shelf Life Extension Technologies
Food Security: Postharvest Losses
Food Security: Yield Gap
Food Toxicology
Forage Crops
Global Agriculture: Industrial Feedstocks for Energy and Materials
Green Revolution: Past, Present, and Future
Medicinal Crops
Organic Agricultural Production: Plants
Organic Livestock Production
Precision Agriculture: Irrigation
Public–Private Partnerships in Agroforestry
Root and Tuber Crops
Sensory Science
Simulation Modeling: Applications in Cropping Systems
Slum Livestock Agriculture
Small Ruminants in Smallholder Integrated Production Systems
Spices and Aromatics
Sugar Crops
Terroir: The Application of an Old Concept in Modern Viticulture
Tree Fruits and Nuts

Animal Health

Animal Health: Ectoparasites
Animal Health: Foot-and-Mouth Disease
Animal Health: Global Antibiotic Issues
Animal Health: Mycotoxins
Animal Health: Tuberculosis
Animal Welfare: Stress, Global Issues, and Perspectives
Biosecurity and Equine Infectious Diseases
Detection and Causes of Bovine Mastitis with Emphasis on *Staphylococcus aureus*
Emerging Zoonoses in Domesticated Livestock of Southeast Asia
Invasive Aquatic Animals
Marek's Disease and Differential Diagnosis with Other Tumor Viral Diseases of Poultry
Poultry and Avian Diseases
Quarantine and Biosecurity
Swine Diseases and Disorders
Vaccines and Vaccination Practices: Key to Sustainable Animal Production
Zoonotic Helminths of Livestock

Plant Health

Climate Change and Plant Disease
Emerging Plant Diseases
Integrated Pest Management in Tree Fruit Crops
Invasive Species: Plants
Mineral Nutrition and Suppression of Plant Disease
Pathogen-Tested Planting Material
Plant Abiotic Stress: Salt
Plant Abiotic Stress: Temperature Extremes
Plant Abiotic Stress: Water
Plant Biotic Stress: Weeds
Plant Disease and Resistance
Plant Health Management: Biological Control of Insect Pests

Plant Health Management: Biological Control of Plant Pathogens
Plant Health Management: Crop Protection with Nematicides
Plant Health Management: Fungicides and Antibiotics
Plant Health Management: Herbicides
Plant Health Management: Pathogen Suppressive Soils
Plant Health Management: Soil Fumigation
Plant Health Management: Soil Solarization
Quarantine and Biosecurity
Soil Fertility and Plant Nutrition

Agriculture and Science

Advances in Animal Biotechnology
Agbiotechnology: Costs and Benefits of Genetically Modified Papaya
Biotechnology Crop Adoption: Potential and Challenges of Genetically Improved Crops
Biotechnology: Herbicide-Resistant Crops
Biotechnology: Pharming
Biotechnology: Plant Protection
Biotechnology: Regulatory Issues
Breeding: Animals
Breeding: Plants, Modern
Cloning Animals by Somatic Cell Nuclear Transplantation
Cloning: Plants – Micropropagation/Tissue Culture
Domestication of Animals
Domestication of Plants
Genebanks: Past, Present, and Optimistic Future
Genomics of Food Animals
Genomics: Plant Genetic Improvement
Heterosis in Plants
Plant Cloning: Macropropagation
Plant Virus Control by Post-Transcriptional Gene Silencing
Regulatory Challenges to Commercializing the Products of Ag Biotech
Stem Cells
Transgenic Methodologies – Plants

PREFACE

Food is absolutely necessary for human existence, yet for most in wealthy nations it is largely taken for granted because of its abundance. Sufficient food is a concern, however, for about 1 billion of the earth's inhabitants today who often go to bed hungry. Food security in a broad sense is becoming a worry of the future for those who understand the limitations of our earth's ecosystems. Malthusian prophecies have so far been wrong, but there is growing concern that we are rapidly reaching the point where feeding the world's growing and richer population will be at the cost to our environment that is unacceptable. In the next few decades we face the challenge of growing more food, with less water, with less fertilizer on less land – because of the growth of urban areas on prime agriculture land. We also face the largely unknown consequences that global warming will have on agricultural production. During the last century agricultural scientists were able to bring cutting-edge science into traditional agricultural practices and increase food production sufficiently to prevent global food shortages. The hope that new scientific discoveries will provide the means to keep ahead of world food demand is complicated by a growing public discomfort with biotechnology being applied to food production.

The concept of services being provided by the ecosystems of the earth is a fairly recent attempt to understand and place value on functions of natural lands that have historically been assumed to have few limits. In the past, if more food was needed, new lands were converted from forests or steppe lands into farm land and new water systems developed to provide the water needed for agriculture. When human populations were low our activities were largely buffered by the abundance of forest and steppe, but too late, we are beginning to understand that these provisioning services of our ecosystems are being overused and are no longer buffered by the abundance of wild lands and waters. We are rapidly losing our planet's biodiversity, irreplaceable ground water is being unsustainably consumed, and major river systems are being overused and polluted. Our oceans, the last place on the planet that still support our hunter and gathering traditions may not be able to sustain these activities into the future. And, food production and processing activities contribute to the greenhouse gas emissions that are rapidly warming our planet. Agriculture is the single greatest user of the earth's land and water resources. In the concept of ecosystem services, provisioning or providing food for all organisms is one of the services provided by ecosystems. Human population growth has and will continue to overtax the ecosystems we inhabit. The ultimate outcome of this major diversion of nature's resources into provisioning the human species is unknown, but it is critically important for us to understand what we must do to sustain our planet.

The breakthrough discovery about 10 000 years ago that plants and animals could be bred to provide a more abundant and secure food source was the foundation upon which all other human activities were able to flourish. Activities other than finding food now became possible and our diverse cultures were able to develop because of agriculture. Until fairly recently, however, the majority of the population of most nations was still directly involved in producing food. Mechanization of agriculture and continued improvements in genetics, fertilizers, and pesticides made food production very efficient in developed nations. In the United States, the leading nation in value of agricultural exports, less than 2% of the workforce is currently employed in producing food. The United States, however, is alone among the most populous nations of the world in having such a small population employed as farmers. In countries such as China, India, Indonesia, and Nigeria the majority of people are rural and involved in agriculture either directly or indirectly. But, as food production becomes more efficient in these countries, and as wages increase in other sectors, a major shift is occurring from rural to urban occupations. This revolution is potentially as important in affecting our cultures and community structures as was the development of agriculture. Many nations are currently experiencing a very rapid transition from rural to urban living with all of the social and logistic problems associated with such rapid structural changes. While this transition in our social and cultural structures is a broad subject, it does have significant impacts on agriculture and our food systems. To mention just a few, agriculture labor, food transport, food safety, and access to healthy food.

There is genuine concern among agricultural scientists that human populations and changing diets are outpacing our ability to meet the increasing food needs of the planet. In the first iteration by Academic Press in 1994 of the *Encyclopedia of Agricultural Science*, Noble Prize Winner Normal Borlaug wrote in its forward:

> Had the world's 1990 food production been distributed evenly, it would have provided an adequate diet (2350 calories, principally from grains) for 6.2 billion people – nearly one billion more than the actual population. However, had the people in Third World countries attempted to obtain 30% of their calories from animal products – as in the United States, Canada, or European Economic Community countries – a world population of only 2.5 billion people could have been sustained – less than half of the present world population.

The issue raised by Dr. Borlaug is probably the most important challenge we face. Human behavior and the food choices of consumers will determine the outcome of the race between food supply and population. Population control has been advocated for decades, and in some cases has become part of national policy, but the world's population continues to grow. Science breakthroughs cannot solve our food security and environmental quality challenges if consumers reject food that is not traditionally produced. Likewise, if meat products and other inefficiently produced food continue to be in high demand by consumers, there will be increased pressure on our food production systems. As supplies become short, prices rise. While this may be good for farmers, high food prices and food shortages will probably undermine our efforts to preserve the

world's remaining arable land as natural lands. We must change human behavior to solve the problems we face.

Food choices, nutrition, diets, food cultures, water and air quality, GMOs, global warming, food security, and similar topics are daily in the news throughout the world. We are all concerned about these issues, yet with all of the information easily available in the popular media about food there seems to be too little informed discussion on these various topics. In planning the *Encyclopedia of Agriculture and Food Systems* the editorial committee chose to organize the topics primarily by issues, rather than to focus on a traditional topic approach. We organized the issues that would be discussed in the chapters around the broad topics of Agriculture and People, Agriculture and the Environment, Agricultural Products, Plant Health Management, Animal Health Management, and Agriculture and Science. The issues raised in this preface are the ones that we felt needed to be addressed in this encyclopedia.

The associate editors joined me in the development of topics for the encyclopedia and were responsible for working with the authors – they deserve particular recognition. I was fortunate to be joined by a very distinguished group of colleagues who, I hope, are still friends. They spent much more time and effort in bringing this project to completion than any of us anticipated. I want to thank our authors who while overly committed and overworked, fulfilled their commitments to contribute to this work. I have been impressed with the quality of their contributions. The editorial staff of Elsevier have had the professionalism and patience to work with scientists who do not work under the same time and budget constraints that the staff work. I want to particularly thank Kristi Gomez, Donna de Weerd-Wilson, and Simon Holt who, each in succession, oversaw this effort, and I especially thank the project managers, who worked directly with me, and the associate editors, Kate Miklaszewka-Gorczyca, Will Bowden-Green, and Sam Mahfoudh.

Glossary

Clone A cell, group of cells, or organism that is produced asexually from and is genetically identical to a single ancestor.
Genetic marker Gene or other identifiable portion of deoxyribonucleic acid (DNA) whose inheritance can be followed.
Marker-assisted selection (MAS) The use of DNA markers to improve response to selection in a population. The markers will be closely linked to one or more target loci, which may often be QTL.
Nuclear transfer A laboratory procedure in which a cell's nucleus is removed and placed into an oocyte with its own nucleus removed so the genetic information from the donor nucleus controls the resulting cell. Such cells can be induced to form embryos.
Quantitative trait loci (QTL) Stretches of DNA containing or linked to the genes that underlie a quantitative trait.
Quantitative traits Traits that vary continuously and are affected by multiple genes or loci. Examples include height and weight.
Recombinant DNA A m1olecule formed by joining DNA of interest to vector DNA.
Single nucleotide polymorphism (SNP) A DNA sequence variation at only one base pair between synonymous pieces of DNA.
Transgenics Organisms that have foreign DNA stably integrated into their genome.
Xenotransplantation The act of transplanting or grafting tissue or organs from an individual of one species into an organism of another species, genus, or family. A common example is the use of pig heart valves in humans.

What is Animal Biotechnology?

Animal biotechnology is any technological application that utilizes animals to make or modify products. The practice of animal biotechnology began more than 8000 years ago when humans began domesticating and selectively breeding animals. The modern era of animal biotechnology arrived following the discovery of the genetic code in the mid 1950s. Today new tools including increased computing power, genomic sequencing, cloning, regenerative medicine and direct gene insertion, and manipulation have given people the potential to dramatically alter animals for a broad range of purposes, including food production, medical, and scientific research. Modern biotechnology represents the intersection of man's manipulation of the environment and the emergence of molecular and computing technologies. These advances, as well as the US Supreme Court ruling that designed life could be patented, have spawned new ways of expediting the use of animals in serving society.

Earliest Animal Biotechnology

Prehistoric humans were originally hunter-gatherers who nourished themselves by following the migration of animals and ripening of foods such as wild fruits and berries. Hunter-gatherer communities could not support high population densities in part, because food resources were not steady or predictable. It is believed that the end of the ice age approximately 10 000 BC created conditions suitable for the transition from a hunter-gatherer lifestyle to farming communities. This transition, known as the Neolithic Revolution, marked the beginning of early agriculture. The Neolithic Revolution is believed to have occurred independently in seven to nine major centers, including Mesopotamia, China, Mesoamerica, and East and West Africa (Von Baeyer, 2010). Most accounts identify Mesopotamia, also known as the Fertile Crescent, as the origin of early agriculture. Owing to its impact on civilization, the transition from hunter-gatherer to farmer has been described as the most important technological development

Table 1 Domestication centers of the world

Center of domestication	*Dates (years ago)*
Near East/'Fertile Crescent'	11 000
Northern China	9 000
Southern China	8 000
Central Mexico	5 750
Peruvian Andes	5 250
Papau New Guinea	6 000–9 000
West Africa	4 500
Eastern North America	4 000

ever to occur in human history. By becoming farmers, humans were able to gather in greater numbers, have better and more consistent nutrition and develop technology. **Table 1** shows the major centers of domestication in the world.

Scientists believe crop domestication preceded the earliest domesticated animals by approximately 1000 years. In East Asia, rice, millet, and soy were domesticated; in sub-Saharan Africa, millet, sorghum, and African rice were domesticated; and in the Americas potato, sweet potato, corn, squash, and beans were domesticated (Floros *et al.*, 2010). The domestication of cattle, sheep, and goats took place 8000, 11 000, and 10 000 years ago, respectively, whereas buffalos, horses, asses, and camels were domesticated approximately 5000 years ago (Hirata, 2004). These animals were considered suitable for domestication because of their docile temperament, willingness to be dominated, and ability to live in large groups.

As humans became sedentary, they began caring for and controlling wild animals and plants for food production, transportation, protection, production of valuable commodities (cotton, silk, or wool), warfare, and companionship. Domesticated animals that we commonly use today, including dogs, cats, sheep, geese, camels, cattle, pigs, and horses started as wild animals but were changed over time through domestication practices (Zeder *et al.*, 2006; Andersson, 2011).

Domestication is not an instantaneous event. It is a cumulative process characterized by changes in which partner populations become interdependent over time (Zeder *et al.*, 2006). This process is also shaped by the particular environmental, biological, and behavioral profiles of the target species, as well as the cultural context of the human societies involved. The typical changes caused by the domestication process can be external or internal morphological changes, such as modifications in body size, decreased brain size, physiological changes, developmental changes, and behavioral changes, such as reduced fear (Jensen, 2006).

Although domestication initially had a small influence on the economies of human societies, which were originally based on hunting and gathering, it enabled these societies to grow in size and to expand into new and more-challenging environments. For example, the domestication of plants and animals enabled human population to grow by providing a food surplus. Moreover, domesticated dogs and sheep enabled human societies to become pastoral. Farming and raising livestock permitted the creation of permanent communities in place of the temporary ones prevalent in migratory hunter-gatherer groups, and the building of permanent shelters to house livestock and store harvested crops. In addition, new farming tools and technologies were developed once people started to grow their own crops (Zeder *et al.*, 2006; Jensen, 2006).

Fewer than 20 animal species have been successfully domesticated (Diamond, 1997), only 7 of which (cats, dogs, cattle, sheep, goats, pigs, and horses) are found worldwide. As pointed out by Hale (1969) and Diamond (1997), animals that have been successfully domesticated and farmed share and exhibit a unique combination of characteristics. They are relatively docile, flexible in their dietary habits, grow, and reach maturity quickly on an herbivorous diet, and breed readily in captivity. They also have hierarchical social structures that permit humans to establish dominance over them and are adapted to living in large groups. They do not include species that generally have a tendency to be fearful of humans or disturbed by sudden changes in the environment. Our ancestors no doubt based their selection methods for improving their herds and flocks on how easy the animals were to farm, as well as on potential agricultural value. In turn, the animals adapted to thrive in a domesticated environment.

Dogs (*Canis lupus familiaris*) were the first animal species to be domesticated, probably in East Africa and Asia. According to archeological evidence, dogs first began to show differences in appearance compared to wolves approximately 15 000 BCE. Many researchers believe that dogs essentially domesticated themselves by scavenging near human camps. Humans then bred them to bark in warning and for reduced aggression compared to wolves (Gray *et al.*, 2009; Skoglund *et al.*, 2011).

Sheep (*Ovis aries*) were probably first domesticated approximately 15 000–11 000 BCE. Their remains have been found at a wide range of sites of early human habitation in the Middle East, Europe, and Central Asia (Chen *et al.*, 2006; Chessa *et al.*, 2009). According to deoxyribonucleic acid (DNA) and mitochondrial DNA (mtDNA) studies of European, African, and Asian domestic sheep, it is believed that they descended from at least three different subspecies of the wild mouflon (*Ovis gmelini* spp.) and that there are three major and distinct lineages: Type A or Asian, Type B or European, and Type C, which has been identified in modern sheep from Turkey and China. Initially sheep were domesticated mainly for meat production. Later, these animals were also used to provide milk, wool, and leather. Nowadays, sheep continue to be important agricultural animals, as well as model organisms for scientific research (Chen *et al.*, 2006; Chessa *et al.*, 2009; Pedrosa *et al.*, 2005).

Goats (*Capra hircus*) were domesticated for their milk and meat, as well as materials for clothing and building (hair, bone, skin, and sinew). Their dung was also used for fuel. They are thought to have been domesticated in Iran and neighboring countries approximately 10 000–11 000 BCE. Recent mtDNA research has shown that all modern goats probably descended from a wide range of animals and may have been domesticated in a variety of different places (Fernández *et al.*, 2006; Luikart *et al.*, 2001).

Pigs (*Sus scrofa domesticus*) have mostly been domesticated for meat production; however their bones, hide, and hair are also used for items such as weapons and brushes. Domestic pigs, especially pot-bellied pigs, are also kept as pets. Archeological studies have shown that the domestic pig was domesticated from wild boars approximately 13 000 BCE in

the Tigris basin. However, remains of domesticated pigs have been found in southeast Anatolia dated to earlier than 13 000 years BCE (Vigne *et al.*, 2009). According to DNA evidence from Neolithic pigs, domesticated pigs were brought west to Europe. Zooarchaeological evidence suggests the domesticated pig was also brought east to China from the Near East, in addition to a separate domestication in China that took place approximately 10 000 years ago. These findings have led to the conclusion that pig domestication occurred independently in several places across Eurasia (Larson *et al.*, 2007; Chen *et al.*, 2007).

Cattle (*Bos primigenius*) have been domesticated since at least the early Neolithic for their meat, milk, leather, dung for manure or fuel, and for use as load-bearers and to pull plows. According to archeological records and modern genetics research for the domestication of wild forms of cattle, the process occurred independently from as few as 80 aurochs (the now-extinct predecessor of cattle) in Mesopotamia approximately 10 500 years ago near the villages of Çayönü Tepesi in southeastern Turkey and Djade al-Mughara in northern Iraq (Allan and Smith, 2008; Ajmone-Marsan *et al.*, 2010; Beja-Pereira *et al.*, 2006).

In addition, several other animal species also went through a process of domestication, such as farmed fowl (chickens, geese, and turkeys), horses, aquatic animals, and some insects. All of them, like those mentioned above, are of great importance to humans, providing products and inputs used routinely.

Assisted Reproductive Technology

Since animals were first domesticated, many technologies have been developed to select for desirable qualities, make breeding easier, and make animals produce more offspring. Many of those technologies, including artificial insemination, *in vitro* fertilization (IVF), embryo flushing, and cloning, involve the manipulation of animal reproduction.

Artificial Insemination

History of artificial insemination

Artificial insemination refers to the introduction of semen and viable sperm into the female reproductive tract via artificial means. Lazzaro Spallanzani, a French physiologist, was the first person to successfully demonstrate artificial insemination in animals, when he artificially impregnated a dog in 1784. However, the use of artificial insemination for commercial purposes began in 1937, when the first artificial insemination cooperative was established in the US. Artificial insemination is still widely practiced today; approximately 60% of dairy cows in the US are bred by artificial insemination.

Spermatozoa extraction and storage

Although many different animals require different methods of artificial insemination, the basic premises remain the same. First semen must be extracted from the male. There are a variety of extraction techniques; however, most often a mechanical breeding mount containing an artificial vagina is used. In the case of dairy cattle, the bull is allowed to first mount a live cow, which is known as the teaser animal. The bull is allowed to repeatedly mount the teaser animal without ejaculating. After a few live mounts, the bull is now directed to an artificial vagina and ejaculation is allowed to take place. The teaser animal serves to increase the amount of viable sperm per ejaculation. After ejaculation, the sperm is collected and sperm sorting may be applied. The sperm is sorted into a male and female population by a flow cytometer, and is typically 90–98% accurate for most breeding species. Sperm sorting is primarily reserved for industries where one sex is more valuable, such as the dairy industry where females are required for milk production. Because one ejaculation contains exponentially more sperm than is necessary for fertilization, an extender solution is added to the semen for dilution and freezing purposes. Depending on the fate of the semen, the extender can be composed of a variety of ingredients. Extenders typically contain milk or egg yolk to protect against cold shock, cryoprotectants such as glycerol, buffers to protect against pH changes, and energy sources for the sperm such as glucose. It is also common for extenders to contain antibiotics to protect against contamination. Once the extender is added to the semen, the semen is frozen down in multiple plastic tubes known as straws. The straws are stored in liquid nitrogen at −196 °C until they are needed for insemination. These advances in cryopreservation of semen have greatly advanced the practice and prevalence of artificial insemination.

Insemination procedure

The female's estrous cycle must be continuously monitored to detect when the animal reaches her estrus phase and thus is ready for the insemination procedure. This estrus phase is also referred to as the 'heat phase' of the female because she is sexually receptive to males. Many behavioral and physical signs indicate the animal is in estrus. The most prominent sign is the standing position the animal assumes, which is referred to as 'standing heat.' This is a natural position the female assumes to be mounted by the male. Other physical indicators of estrus are swelling and reddening of the vulva, discharge of mucous from the vagina, and increased affectionate behavior toward other animals. Because ovulation occurs at the end of the estrus phase, the most efficient and effective time for sperm deposition is 12–26 h after the onset of estrus. This ensures that the sperm are viable in the uterus before ovulation occurs, which leads to a higher conception rate. To make breeding more efficient and simple, many cattle farmers practice estrus synchronization. Estrus synchronization is the practice of synching a female population's estrus cycles through the injection of natural and artificially synthesized hormones. Once the animal is ready for insemination the sperm must be properly thawed and loaded into the insemination catheter or gun. For most species, the sperm should be thawed to 36.7 °C for optimal results. It is also crucial that the sperm not be thawed for more than 10 min, as exceeding this threshold leads to infertile sperm. There are a variety of insemination techniques, and the ideal location for sperm deposition varies between species. Generally, depositions in the uterus lead to a higher conception rate versus deposition in the vagina and cervix (Dalton, 1999). Transcervical insemination is a common technique used among many animals and is

preferred because it does not require surgery. Transcervical insemination utilizes an endoscope to locate the cervix and then a catheter is passed through the cervix into the uterus for sperm deposition.

Advantages of artificial insemination

Artificial insemination has opened numerous doors for animal biotechnology in the past 80 years. Perhaps the greatest advantage conferred by artificial insemination is the ability to quickly pass desirable traits to many offspring. Artificial insemination is also extremely cost-efficient, as sperm can be collected and shipped all across the world. This reduces the need for many breeding grounds to house and maintain male animals. Not only does this reduce costs, but it also provides a safer environment because males can be aggressive and become a safety threat. Other advantages include higher conception rates, the elimination of many genital diseases, and more comprehensive records of animals.

In Vitro Fertilization

History of in vitro fertilization

IVF refers to the fertilization of an ovum by a spermatozoon outside of the body. Research on the possibilities of animal IVF began in the late 1800s, whereas the first attempts at animal IVF began in the early 1930s (Bavister, 2002). The first attempts used rabbit oocytes and spermatozoa, but were unsuccessful. In 1951 the discovery of sperm capacitation by researchers Austin and Chang explained why those initial experiments failed: Spermatozoa need to develop and undergo changes in the female reproductive tract before fertilization can occur (Bavister, 2002). This discovery enabled Chang to successfully fertilize rabbit oocytes *in vitro* using sperm that was capacitated *in vivo*. This led to the first mammalian IVF birth, a rabbit born in 1959 (Brackett, 2001). However, it was approximately 20 years later when the first successful mammalian IVF was performed using spermatozoa capacitated *in vitro*. Today, IVF is still being heavily researched and the full extent of its promises for animal biotechnology has not been reached. However, it has already greatly increased researchers' knowledge of animal reproductive mechanisms. Commercially, the bovine industry has seen the greatest impact from IVF. Hundreds and thousands of bovine embryos created via IVF are sold and exchanged worldwide each year.

Oocyte extraction and fertilization

Like every assisted reproductive technique, the actual mechanics will vary among species. Regardless of which technique is employed, five basic steps define IVF. They are (1) superovulation of the oocyte donor, (2) immature oocyte collection, (3) oocyte maturation *in vitro*, (4) mature oocyte fertilization, and (5) embryo development and growth *in vitro*. Superovulation is achieved in the donor animal through the injection of gonadotropins. Immature oocytes are typically collected in the form of cumulus–oocyte complexes (COCs) either from a live animal or from the ovaries at a slaughterhouse. If the immature oocytes come from a live donor animal, this is most often performed by a procedure called transvaginal oocyte recovery. Transvaginal oocyte recovery is a nonsurgical technique that employs an ultrasound probe, a vacuum pump, and a needle aspiration system to collect the COCs. Once the COCs are collected, they are placed into an oocyte maturation medium, which can contain numerous hormones and other reagents. This medium mimics the *in vivo* environment that induces meiosis of the oocytes, thus arresting them in metaphase II and preparing them for fertilization. Once the oocytes have matured, they are ready for fertilization. The oocytes must be washed before fertilization to ensure that all hormones and unwanted reagents from the maturation medium are removed. Likewise, the spermatozoa must also be purified from the extender and cryopreservation reagents if it came from a frozen straw. Finally, the spermatozoa are screened to ensure they are motile, and a capacitance-inducing medium is added to the spermatozoa. The prepared spermatozoa can be added to the mature COCs to initiate fertilization.

Culture of embryos

Once fertilization occurs, there are a number of different methods to culture the fertilized oocytes. Some species require that the 2–8-cell stage embryos be transferred to the oviduct of a live animal (Havlicek *et al.*, 2005). For *in vitro* culturing, there are numerous protocols that can be used. One method frequently used is a coculture in which the medium contains oviduct cells to replicate *in vivo* conditions. A sequential medium method is also commonly used, where the components of the media are changed depending on the cell stage of the embryos, mimicking the different chemical environments embryos experience as they mature *in vivo*. Many factors affect the development of embryos, including temperature, pH, and gas concentrations. Depending on the researchers' needs the embryos may be used for embryo transfer, the implantation of embryos into viable females, or cryopreserved for shipping or future use.

Embryo transfer in vitro fertilization

After being cultured for 7 days the embryos reach the blastocyst stage and are ready to be transferred to a recipient animal. It is crucial that the recipient animal's estrous cycle be synchronized to the current stage of the embryo. That is, if the embryo is 7 days old, the recipient animal must be close to her 7th day of estrous (Senger, 2003). This ensures that the environment of the uterus is suitable for attachment of the embryo and that proper embryonic development occurs. Embryos can be transferred into the recipient by surgical or nonsurgical means. Nonsurgical methods are preferred because they are quicker and less expensive. The most common form of nonsurgical embryo transfer utilizes a transfer pipette or loading gun to insert the embryo into the uterine horn. When transferring into a cow, the technician often reaches through the rectum to grasp the cervix to help guide the loading gun through. Epidural anesthesia is often used to relax the reproductive tract and make the embryo insertion easier. If the embryo successfully attaches to the endometrium, the recipient will become pregnant.

Advantages of in vitro fertilization and embryo transfer

Like artificial insemination, IVF and embryo transfer allow for the mass production of genetically superior progeny by

allowing females to produce more offspring. These technologies have allowed desirable female donors to produce up to 20 offspring each year. In addition, embryo transfer has allowed for genetically inferior females to be utilized for their birthing capabilities, serving as the recipient female. Embryo transfer also allows for the diversification of species within geographical regions, as embryos can be easily shipped across the globe. This is also a much more cost-efficient and bio-secure method compared to transporting live animals (Senger, 2003).

Embryo Flushing

Instead of fertilizing oocytes and culturing the embryos *in vitro* (as in IVF), embryos are often produced *in vivo* and then 'flushed' out of the uterus. In fact, embryo flushing is much more prevalent and cost-efficient than IVF for the production of embryos. Although the first successful embryo flush and transfer was performed in rabbits in 1890, the procedure is primarily done with cattle today. More cattle undergo embryo flushing each year than all other species combined. Embryo flushing is primarily accomplished by artificially inseminating a superovulated female donor with spermatozoa from a genetically superior male. The embryos are collected from the donor after fertilization occurs, typically within 6–8 days. Bovine embryo collection typically employs a Foley catheter, flushing medium, and a collection vessel. The Foley catheter is inserted into the uterus and the flushing medium is passed through the catheter. The catheter typically contains a small balloon that seals off the uterus and prevents the backflow of the flushing medium. The flushing medium is allowed to flow back out of the catheter and is collected in a vessel. Depending on the success of superovulation and fertilization, the flushing medium may contain 1–30 embryos. The typical yield for cattle that undergo superovulation and artificial insemination is 5–7 viable embryos (Senger, 2003). The embryos can be examined by a microscope for viability and transferred to a recipient or cryopreserved using the same methods previously discussed for IVF.

Advantages of in vitro *fertilization embryo production over embryo flushing*

Although embryo flushing is more cost-efficient than IVF, there are a handful of instances when IVF is preferred or necessary. IVF can generate embryos after the death of an animal by surgical extraction of the oocytes. Oocytes can remain viable for 9–12 h after the death of most species. IVF also must be employed when the female is infertile but still has functional ovaries, often the result of infectious diseases. Another cause of infertility in livestock species is the continuous injection of hormones into females. Many female animals may receive hormonal injections throughout their lifetime. This leads to the inability to generate embryos, but oocytes can still be collected.

An in vitro *fertilization technique: Intracytoplasmic sperm injection*

Intracytoplasmic sperm injection (ICSI) is a form of IVF that utilizes only one spermatozoon and one oocyte. Oocytes are first extracted by the transvaginal oocyte recovery procedure. Under high-powered magnification, the oocyte is held by a micropipette while the spermatozoon is injected into it. Once fertilization occurs, the zygote is allowed to mature *in vitro*. Although ICSI has only been around for the past 25 years, many domesticated animals have been reproduced through the procedure, including cattle, pigs, horses, and sheep (Horiuchi and Numabe, 1999). However, the procedure requires more expensive technology and labor than other assisted reproductive techniques, and therefore it is mainly used for research purposes. There are situations where ICSI is used for reproductive purposes, although it is primarily after standard IVF has not been effective. Standard IVF is typically ineffective when the spermatozoa are defective, either because they are nonmotile or cannot complete the acrosome reaction. ICSI remains an inefficient breeding technology and is not as reliable as standard IVF in most domesticated animals even though recent advances have made ICSI more successful. One such advance has been the use of piezo-actuated micromanipulation during ICSI. Piezo-actuated micromanipulation entails rapid and precise insertion of the spermatozoon in response to an externally applied voltage. Piezo-actuated micromanipulation has been shown to improve ICSI fertility in numerous species, including mice and cattle.

Cloning

History of cloning

Although recent advances have opened bountiful opportunities and discussions on animal cloning, cloning experiments have been taking place for more than 100 years. An animal clone is broadly defined as an animal that originates from another animal, and both animals share identical chromosomal DNA. Hans Dreisch created the first animal clones in the late 1800s. He created sea urchin clones by splitting a two-cell embryo and allowing both cells to independently develop into sea urchins. These embryo-splitting experiments continued into the 1900, led by the Nobel Prize winning Hans Spemman's work on salamander embryos. The next major advance came in 1952 when Robert Briggs cloned a frog using a new technique; he used nuclear transfer to transplant the nucleus of a blastomere from a frog embryo into an enucleated egg. Although Briggs showed embryonic nuclear transfer could produce clones, not many believed that adult somatic cells could be used as donors. However, in 1996 the largest breakthrough in animal cloning came in the form of a sheep named Dolly. Dolly became the first animal to be cloned using the nucleus of a differentiated adult cell as a donor. Dolly opened the door to cloning via somatic cell nuclear transfer (SCNT), and many other species have been cloned in the last few decades.

Somatic Cell Nuclear Transfer Procedure

Along Came Dolly

Dolly, the world's most famous sheep, became a sensation in 1996. Dolly was famous because she was the first animal clone that originated from an adult somatic cell. Scientists Ian Wilmut, Keith Campbell, and

their colleagues at the Roslin Institute in Scotland created Dolly from an udder cell of a 6-year-old Finn Dorset white sheep. The udder cell was inserted into an enucleated oocyte of a Scottish Blackface ewe. Once it is was confirmed that the embryo was undergoing normal development at day 6, it was inserted into a different Scottish Blackface ewe. In a sense you could say Dolly had three mothers. On 5 July 1996, 148 days after embryo transfer, Dolly was born as 'a normal vigorous lamb and was standing and sucking unaided within minutes.' When asked how Dolly got her name, Dr. Wilmut responded, 'Dolly is derived from a mammary gland cell and we couldn't think of a more impressive pair of glands than Dolly Parton's.' Out of 277 cell fusions, 29 embryos produced, and 13 surrogate mothers, Dolly was the only live offspring born from Wilmut's experiment. Dolly lived for 6 1/2 years and was euthanized on 14 February 2003. She suffered from an incurable disease known as sheep pulmonary adenomatosis (SPA). SPA is caused by a virus that induces lungs tumors in affected sheep. Dolly's death was not directly caused by her being a clone, as other sheep in Dolly's vicinity died from the same virus. In Dolly's 6 1/2 years she gave birth to 6 offspring, battled arthritis, and was found to have shortened telomeres. Dolly shattered the theory that differentiated cells lose their ability to develop into other cell types. Dolly proved that cell differentiation is not simply a one-way process, and most somatic adult cells are capable of being reprogrammed into any other cell type.

SCNT is now the primary method used in animal cloning. The procedure first begins by extracting oocytes from a female donor and allowing the oocytes to mature *in vitro*. Once an oocyte has matured the nucleus can be removed using a needle aspiration system. The enucleated oocyte is now ready to accept the donor cell. There remains healthy debate concerning whether the donor cell should undergo a serum starvation treatment before being inserted into the oocyte, as well as the significance of the type and age of the cell used. The serum starvation treatment arrests the donor cell in the G0 phase, stopping further division. Once a donor cell is selected it can be inserted under the zona pellucida of the oocyte. The two cells are fused together by a brief electrical stimulus, which is referred to as electrofusion. The developmental and directing factors of the ooplasm reprogram the somatic nucleus to develop into an embryo and eventually a blastocyst, after which it can be transferred into a recipient.

Current State of Animal Cloning

Cloning on the Wild Side

Some scientists are investigating the use of cloning technology as an option to save endangered species and even resurrect extinct ones. Russian and South Korean scientists have been working together to try to clone a woolly mammoth using cells recovered from 10 000 years old frozen remains of a baby woolly mammoth. The scientists plan to clone the mammoth by extracting nuclei from the frozen mammoth cells, transferring them to elephant eggs and stimulating the cells to start dividing. The resulting embryos would be implanted into elephant wombs for gestation.

Brazilian scientists also aim to clone endangered animals. A project designed by scientists from the agricultural research agency Embrapa, together with the Brasília Zoological Garden, will attempt to clone and hybridize jaguars, collared anteaters, maned wolves, and other endangered species. Somatic cells and spermatozoa from eight threatened species have already been collected. The researchers must now receive permission from the government to conduct experiments on the 420 samples already collected. Several environmentalists are concerned about this project because these cloned, hybridized, and captive-bred animals, if mixed with wild populations, could result in potential environmental risks. However, the project was specifically designed to supply zoos rather than replenishing wild populations.

The cloning of endangered species has raised several issues between conservationists and environmentalists, who say that instead of cloning to save these species, more efforts to protect and recover their natural habitats should be made. They believe that conserving the natural habitat where these animals live would have a greater impact on the preservation of these species.

The potential advantages of cloning are innumerable for many industries including agriculture and biomedical research. However, the field is still relatively new and needs extensive research to make animal cloning more efficient. Cloning efficiency is defined as the number of live offspring per embryos transferred. Currently, the efficiency rate for cattle is 6–15% and 6% for pigs. However, for some animals the efficiency is as low as 1–2%, whereas others still have not been successfully cloned (Fiester, 2005). Although cloning efficiency has improved in the past 10 years, these proportions are still substantially lower than other reproductive techniques. In addition, some clones are born with phenotypic abnormalities. The most common abnormality is an unusually increased birth weight, known as large offspring syndrome (LOS). LOS causes difficulties in the birthing process, as well as other health risks for the animal, such as organ defects and diabetes. These abnormal phenotypes are not transmitted to the clone's offspring, which suggest *in vitro* conditions alter the epigenetic patterns of the cloned embryo, as these patterns are reprogrammed during gametogenesis (Prather *et al.*, 2004). These *in vitro* conditions are being studied to help improve efficiency and reduce abnormalities in animal cloning, as a number of biological factors are known to influence the reprogramming of the nucleus.

Production of Transgenic Animals

Inserting human genes into an animal's genome allows animals to produce important human proteins, such as the blood clotting agent factor IX. However, the methods for producing transgenic animals are not very efficient. Incorporation rates of the new gene into their genome are low and occur at random sites which often do not allow the gene to be expressed. Also, the insertion can cause disruption in the expression of another gene. Researchers at the Roslin Institute sought to use cloning as an efficient way to produce transgenic animals. In theory, once a cell line successfully incorporates and expresses a transgene, that cell line can be used as a donor cell for cloning. The clones produced will have the transgene incorporated into their genome and can successfully pass it to their offspring through traditional breeding methods. This could lead to entire herds of transgenic animals expressing important genes for medical and agricultural purposes. Transgenics and cloning also hold enormous potential for

producing organs in animals for human transplants, or xenotransplantation. If animals can be modified to produce viable organs for humans, cloning could drastically increase the human organ supply.

Genome Editing

Precision Editing Opens a World of Possibilities for Transgenics

The precision of nuclease-based genomic editing can lead to custom designed animals with improved traits and modifications to better serve as human disease models. Cow's milk allergy (CMA) is an immunologically mediated allergic reaction to certain proteins in cow's milk. The CMA-inducing protein beta-lactoglubulin causes diarrhea and vomiting in children. It is estimated that the prevalence of CMA varies between 0.25% and 4.9% and is higher in children than in adults. For the last few decades researchers have been trying to create transgenic cows that produce beta-lactoglobulin-free milk, but have been unsuccessful because of a lack of precision associated with gene editing. Recently researchers found a gene encoding microribonucleic acid (miRNA) in mice that targets beta-lactoglubulin mRNA and silences its production. This technology is known as RNA interference (RNAi), and it allows for the elimination of beta-lactoglobulin protein without needing to alter the gene itself. After successfully inserting the miRNA gene into the genome of cow embryos, one calf was born that produced beta-lactoglobulin-free milk.

Although RNAi is effective at silencing genes, it cannot eliminate the protein completely. Transcription activator-like effector nucleases (TALENs) are artificial restriction enzymes created by the fusing of a DNA binding domain with a DNA cleavage molecule. TALENs work by cutting DNA at specific sequences, introducing double-stranded breaks into a gene of interest. When the cells repair the breaks they introduce mutations into the gene that can render the gene nonfunctional. In pigs, TALENs have been used to disrupt genes encoding low-density lipoprotein (LDL) receptors. Pigs lacking these receptors are unable to remove LDL from the bloodstream, causing them to develop atherosclerotic arteries. Such pigs can be used as disease models to aid biomedical research in human atherosclerosis.

Many transgenic technologies are inefficient because they involve nonspecific integration of the transgene into the target genome. In contrast, nuclease-mediated genome editing results in a specific integration. The method relies on the use of artificial proteins made up of customizable, sequence-specific DNA-binding domains fused to a nuclease that cuts DNA in a nonsequence specific way (Joung and Sander, 2013). Zinc-finger nucleases (ZFNs) and recently, TALENS are employed in performing targeted genome editing. ZFNs and TALENS can be described as molecular scissors that cleave double-stranded DNA at a specific site in a predetermined sequence of the genome. The cleavage triggers DNA repair that can be exploited to modify the genome either by targeted introduction of insertions and deletions (gene disruption), base substitution specified by a homologous donor DNA construct (gene correction), or the transfer of entire transgenes into a native genomic locus (Urnov *et al.*, 2010). This new technique has the potential to be used in many applications including therapeutic approaches to treat genetic disease, production of model organisms, and generation of new agriculturally relevant varieties.

Transgenic Technologies for Food and Other Products

Transgenic Animals Can Provide New and Improved Products

Farmers have been using selective breeding to increase desirable traits in agricultural animals since the dawn of domestication. However, the increased production potential possible from traditional selective breeding practices is limited. Advances in molecular biology have made it possible to develop traits in animals quicker and with more precision, allowing farmers an alternative means to increase yields, improve the nutritional value of food products, make animals resistant to diseases, and produce human pharmaceuticals in the milk of transgenic cows, goats, pigs, or rabbits. Some transgenic animals already have been approved by the Food and Drug Administration (FDA) for production of nonfood products, and the AquAdvantage® salmon is close to becoming the first transgenic animal approved by the FDA for human consumption (at the time of publication).

Less smelly pig

From Egg to Plate in Half the Time: Speedy Salmon Promise Profit

AquAdvantage® Salmon are in line to become the first genetically engineered (GE) nonplant food source approved for human consumption by the US FDA. This accomplishment is the culmination of more than 20 years of work, which began during a coffee break. One winter day in the 1980s, when Dr. Choy L. Hew, who studied an antifreeze protein that allows fish to survive subzero temperatures, was chatting with his colleague, Dr. Garth Fletcher. Fletcher was frustrated because he just returned from a fish farm where all the salmon had frozen to death and he challenged Hew to use his molecular biology to do something about this problem. Having limited success enhancing the cold tolerance of the salmon, they altered the plan to increase the growth rate so that they could be harvested before the onset of winter cold. They GE the salmon by attaching the antifreeze protein promoter to the growth hormone gene, causing growth hormone to be produced during the winter months, allowing the salmon to grow year round. They saw the first fast-growing fish in the summer of 1990, and received a patent in 1996. In the same year they met Elliot Entis, who was running his father's wholesale seafood business, at an academic conference. Entis showed a great interest in the fast-growing salmon. He licensed their technology and started A/F Protein. The company, now called AquaBounty Technologies, brought the AquaAdvantge Salmon to a marketable stage. These fish outgrow any wild or farm-raised salmon, and can grow from the egg stage to market weight in 16–18 months, as opposed to 3 years for traditional salmon. The AquAdvantage® salmon are waiting on final approval of the FDA while environmental issues are studied.

One goal of current research is to create transgenic farm animals that are more environmentally friendly. At the University of Guelph in Canada, for example, transgenic pigs have been developed with the issue of manure-related environmental pollution in mind. Referred to as the EnviroPig, this transgenic pig is capable of digesting phosphorus in plants more efficiently than conventional pigs. The EnviroPig contains a bacterial phytase gene controlled by a salivary-gland-specific promoter, which limits the production of phytase to the saliva. Phytase is an enzyme that releases

phosphate from phytate, which accounts for up to 80% of phosphorus content in most feeds. The ability to digest plant phosphorus limits the need for costly feed supplements such as phosphate minerals or commercially produced phytase. In addition, the EnviroPig excretes 30–70% less phosphorus in its waste than conventional pigs. This is environmentally important, as excess phosphate from manure alters the local water environment, causing increased algae growth, production of greenhouse gases, and the death of fish and aquatic animals. The lower levels of phosphorus in pig feces reduce water pollution. The hope for this project was to be able to market the EnviroPig as a more environmentally friendly option with reduced feed costs. The university has applications with Health Canada and the US FDA for the EnviroPig to be approved for human consumption. According to the company website, in 2012, Ontario Pork decided to redirect its research dollars, ending its funding of the EnviroPig program, and the remaining EnviroPigs were euthanized. Ontario Pork's Director of Communications and Consumer Marketing Keith Robbins said of the decision to stop funding of the EnviroPig, "we sort of felt that we weren't getting the kind of return that was originally looked at in concept of that product." The decision ultimately was because of the lack of public demand for genetically modified animals in the food system.

GloFish: GM Pets That Brighten Homes and Hearts

In 2003, Yorktown Technologies created a genetically modified pet. The GloFish®, a fluorescent red zebrafish, has become the first transgenic animal commercially available in the US and a really popular aquarium item. The GloFish is available in five fluorescent colors with the exciting names – Starfire Red®, Electric Green®, Sunburst Orange®, Cosmic Blue®, and Galactic Purple®.

The original zebrafish (*Danio rerio*), from which the GloFish was developed, is native to India and Bangladesh. Because the GloFish was developed from a tropical fish and cannot survive in the colder US waters, it is believed that these GE zebrafish pose no risk to the environment. Because GloFish pose no risk to the environment or entering the food supply, the FDA decided not to regulate these transgenic animals. However, although the GloFish is permitted in the US, the sale of this GM pet is not allowed in the state of California.

The fluorescent zebrafish was primarily developed with the aim to detect pollution by selectively fluorescing when in the presence of environmental toxins. This first fluorescent fish was created in 1999, when Dr. Zhiyuan Gong and his team at the National University of Singapore (NUS) were working with the green fluorescent protein (GFP) gene extracted from jellyfish, which naturally produced bright green fluorescence. This gene was then inserted into a *Danio rerio* embryo and integrated into the zebrafish's genome, allowing the fish to be fluorescent under natural white light and ultraviolet light. Sometime later, these scientists made a deal with Yorktown Technologies to develop the GloFish®.

Although GloFish® pose no risk to the environment, a new variety of the GloFish introduced in February 2012 has raised some concerns. The Electric Green Tetra, a GE black tetra fish, includes genetic material from a fluorescent coral that makes it neon-bright and makes the fish fluorescent when placed under a black light. Some environmentalists and experts are concerned about the new black tetra. If released, this South American fish would be able to survive in the waters of South Florida and Latin America, where they could pose potential environmental risks and have an undesirable influence on natural biodiversity.

More – and better – meat on their bones

The ability to produce transgenic pigs and cattle with enhanced muscle growth is an area of increasing interest. Researchers have been studying the effects of targeting myostatin, the only secreted protein known to negatively affect muscle mass *in vivo*, as well as genes for growth-related hormones and lean muscle mass (Long *et al.*, 2009). Transgenic myostatin knockout cows have been produced in the US; however, there are concerns regarding the increased neonatal morbidity that arises from giving birth to larger calves with increased fetal muscle mass (Tessanne *et al.*, 2012). Currently no myostatin knockout pigs have been developed; however, transgenic pigs for growth-related hormones have been produced. Although they show improvement in growth rate, feed conversion and body fat/muscle ratios, they also showed signs of fatigue, gastric ulcers, and low libido. Transgenic pigs containing insulin-like growth factor-1 and a desaturase gene from spinach have been shown to have increased growth rates and increased levels of polyunsaturated fatty acids, respectively. These new developments come without the negative side effects of previous transgenic pigs. In addition, researchers at the University of Illinois have produced transgenic pigs expressing bovine α-lactalbumin, which leads to an increase in milk production (Wheeler *et al.*, 2001). This increase in milk production was shown to increase the weight gain of piglets suckling from the transgenic gilts compared to control gilts. Gilts are female pigs that have had no more than one litter. When pigs give birth to a second litter, they are referred to as sows. These technologies allow for the decreased use of less effective techniques, such as growth hormones whose residues can be found in the final animal product. Despite these advances, none of these transgenic animals have been approved for human consumption.

Omega-3 fatty acids are found mainly in fish oils and largely considered beneficial to human health. Conventional meat products contain large amounts of omega-6 fatty acids, and low levels of omega-3 fatty acids. Diets with a high omega-6/omega-3 fatty acid ratio are correlated with coronary artery disease, cancer, diabetes, arthritis, and depression. To try and create a healthier balance, researchers have recently developed transgenic pigs and cows containing high levels of omega-3 fatty acids in both their tissue and milk (Lai *et al.*, 2006; Wu *et al.*, 2012). This was done by inserting a gene encoding for an omega-3 fatty acid desaturase into the genome of the pig and cow. Omega-3 fatty acid desaturases are enzymes required for the conversion of omega-6 fatty acids to omega-3 fatty acids. The end result is an increase in omega-3 fatty acids and a decrease in omega-6 fatty acids, thus creating the potential for meat and dairy products with a healthier omega-6/omega-3 ratio.

Not your mother's milk

A team of scientists at AgResearch and the University of Waikato in New Zealand has successfully produced a transgenic cow lacking β-lactoglobulin (BLG) (Jabed *et al.*, 2012). This whey protein is believed to be the main cause of milk allergies in humans, and knocking out this gene could allow for the production of hypoallergenic dairy products. The researchers use miRNA technology to silence the expression of BLG in the milk, making it potentially less allergenic. In addition, high casein levels were reported in the BLG-deficient milk. Casein

makes up 80% of milk protein in conventional cows and is an extremely valuable component of milk because of its nutritional value and processing properties. The increased casein levels associated with this BLG knockout cow could provide increased calcium levels and higher cheese yields. In addition, another group in New Zealand has produced transgenic cows containing additional β- and κ-casein genes (Brophy *et al.*, 2003). These cows have been shown to produce milk with a twofold increase in κ-casein, and up to 20% increase in β-casein levels. The increase in κ-casein has been associated with improved heat stability and cheese-making properties, whereas increased β-casein has been associated with increased milk calcium levels and whey expulsion.

In addition to cows, there is much interest in producing transgenic goats to create healthier milk for human consumption. For instance, changes in the fatty acid composition of milk produced by goats containing a transgene encoding a stearoyl-CoA desaturase (SCD) enzyme has been reported (Reh *et al.*, 2004). SCD works by converting saturated fatty acids into monounsaturated fatty acids. Because one-third of saturated fatty acids in American diets come from dairy products, and saturated fatty acids can lead to increased blood cholesterol levels, leading to increased risk of atherosclerosis and coronary heart disease, the decreased level of saturated fatty acids in milk is an important heath concern. The SCD transgenic goats were shown to have increased levels of monounsaturated fatty acids as well as decreased levels of saturated fatty acids, which could prove to have increased health benefits compared to milk from conventional animals.

Baa baa, transgenic sheep, have you any wool?

Green Pigs Light the Way for Biomedical Research

Dr. Randy Prather is a professor of reproductive biotechnology at the University of Missouri. He has been involved in the push for transgenic pigs in biomedical research, having produced both GFP and yellow fluorescent protein (YFP) transgenic pigs. These pigs contain a GFP gene that comes from a jellyfish, and is commonly used as a molecular marker because it is easily visible under ultraviolet light. Dr. Prather summarizes the importance of this work, saying 'these animals prove that we can make genetic modifications to express desired traits. For xenotransplantation, this is a large step because it means it's possible to change the genetic makeup of the cells to prevent the body's rejection of transplanted organs. However, not everyone is excited about these technological advancements. Kathy Guillermo, a spokeswoman for people for the ethical treatment of animals, believes that transgenic animal experiments like these are unethical and of little use. "On one level, we're just opposed to it period because it's the treatment of animals like objects," Guillermo said. "On another stance, we see it as bad science." Regardless, Dr. Prather and other researchers around the world are hoping transgenic animal models like the GFP and YFP pig will result in advances in the fields of agriculture and biotechnology. "Application of this technology can help feed an ever-growing population, and it can have tremendous potential to alleviate human suffering," Prather said.

In addition to products for human consumption, there are a number of other new, as well as improved products transgenic animals could be utilized for. Increased wool growth in transgenic sheep has been achieved in New Zealand by introducing an insulin-like growth factor-1 gene associated with a keratin promoter (Damak *et al.*, 1996). The keratin promoter allows production of the transgene in the skin and results in an increase in the production of clean fleece weight to conventional sheep. Although no health issues were observed in the transgenic sheep, the staple strength of the wool produced by the male transgenic sheep was lower than that of female transgenic and nontransgenic animals. Further research could result in herds of transgenic sheep capable of higher wool yields than conventional sheep, potentially lowering costs for farmers.

Silk in milk

Transgenic goats are also being produced for dragline silk in their milk. Dragline silk is made by orb spiders and is the strongest known material by weight. Because of its strength as well as its elasticity, there is much interest in large-scale production of dragline silk for use in military uniforms, medical sutures, and tennis racket strings. After failing to produce the material in bacteria and mammalian cell culture, scientists in Canada have successfully inserted the spider silk genes into goat embryos. When the transgenic goats matured, the spider genes were expressed in the mammary glands of females, which began to secrete tiny strands of spider silk in their milk. Once protocols are in place for the purification and spinning, the resulting thread could be used for a number of commercial as well as medical applications.

Biopharming: Transgenic Animal Advances in Medicine and Research

Transgenic animals not only have potential to improve agriculture, but could also lead to significant breakthroughs in biomedical research. For decades proteins such as insulin and human growth hormone have been produced in bacteria and yeast cultures. However, proteins such as blood clotting factors and monoclonal antibodies require complex folding patterns and additional sugar molecules to become biologically active. These sophisticated modifications require the proteins be produced in mammalian cells to be carried out properly, thus showing the limitations of *in vitro* bacterial culture techniques to be able to produce complex proteins. Some examples of transgenic animal systems that are currently being researched include milk, blood, and egg whites.

Complex Protein Production

Transgenic animals in biomedical research can aid in the production and subsequent collection of insulin, growth hormone, blood anticlotting factors, and other biological products in the milk of cows, sheep, and goats. Dairy cows, for example, have a yearly milk output of approximately 10 000 l, making it possible for a single-lactating cow to produce tens of kilograms of therapeutic proteins. Relatively small herds of a few hundred lactating transgenic cows or goats can produce several hundred kilograms of purified protein per year. In fact, it has been estimated that only 60 transgenic pigs would be needed to supply the entire factor IX protein required in the US. This is referred to as biopharming, and is gaining momentum as a potential route for the production of products for medical use.

The first therapeutic protein produced in the milk of transgenic animals to be approved for human use was antithrombin, an anticoagulant protein that can treat patients with a congenital deficiency. GTC Biotherapeutics (Framingham, MA) markets recombinant antithrombin purified from the milk of transgenic goats. In 2006, the European Medicines Agency approved the drug and then in 2009, the US FDA also gave approval. In addition, the production of transgenic pigs whose milk contains human factor VIII and IX, hemoglobin, human protein C, human erythropoietin, human granulocyte-macrophage colony stimulating factor, and Von Willebrand factor are being researched.

In 1997, the first transgenic cow was produced whose milk was enriched with the human protein α-lactalbumin. The transgenic milk, being more similar to human breast milk, is more nutritionally balanced than natural bovine milk and could be given to babies or the elderly with special nutritional or digestive needs. In addition, cows have been produced that secrete human lactoferrin, a glycoprotein involved in innate host defense, in their milk (Van Berkel *et al.*, 2002). Because of lactoferrin's antibacterial, antifungal, antiendotoxin, and antiviral activities, a number of medical uses for this glycoprotein have been considered, such as the treatment of infectious or inflammatory diseases. The ability of these researchers to produce and purify human lactoferrin from the milk of these animals shows the potential of transgenic animals for large-scale production of biopharmaceutical products.

Human Disease Models

An area of biomedical research that has huge potential for transgenic animals is their use as human disease models. Although mice have traditionally been used as the go-to animal model for human diseases, many of the breakthroughs in mice have not translated to humans. Because of their similar size and physiology, there has been increasing interest in using pigs as human disease models. Conventional pigs are already used to study cardiovascular disease, atherosclerosis, cutaneous pharmacology, wound repair, cancer, diabetes, and ophthalmology. Using transgenic technology, pig models are currently being produced for such diseases as Alzheimer's disease, cystic fibrosis, retinitis pigmentosa, spinal muscular atrophy, diabetes, and organ failure (Aigner *et al.*, 2010). Once these animal models have been characterized, new drugs and therapies can be tested before clinical trials.

Xenotransplantation

An estimated 45 000 Americans under age 65 could benefit from a heart transplant each year, but only approximately 2000 human hearts are available. To close this gap, researchers have begun to study xenografts, the transplanting of organs and tissues from animals into humans. Although nonhuman primates such as chimpanzees are genetically closest to humans, reducing the chances of graft rejection, primates are endangered in the wild and their use as a source of replacement organs raises ethical concerns because of their high level of intelligence and the increased risk of disease transmission between such closely related species. As an alternative, some have proposed using pigs as a source of organs because they have large litters, a short gestation time, are anatomically and physiologically similar to humans, are already produced in high volume as a food source, and are currently used to provide some replacement tissues such as heart valves.

Xenotransplantation would have to overcome many technical and ethical obstacles before it can become a reality. One of the first technical issues researchers have focused on are the antigens on the surface of pig cells. These surface antigens are similar to the ABO blood group antigens that trigger severe immune responses called hyperacute rejection. To address this, scientists have inserted human genes into single-cell pig embryos in an attempt to make their cell-surface proteins more similar to human ones so the tissues are no longer antigenic. However, even if this procedure reduces the risk of hyperacute rejection, other immunological barriers to xenotransplantation, such as acute humoral xenograft rejection, thrombotic microangiopathy, and coagulation dysregulation still exist.

In addition, there are concerns of cross-species infections caused by exogenous viruses, such as porcine cytomegalovirus, present in the xenotransplanted organs (Fishman and Patience, 2004). In 1997, Robin A. Weiss, a virologist at University College London, discovered a new class of pig viruses called porcine endogenous retroviruses (PERVs) and determined that they have the ability to infect cultured human cells. The transplantation of a pig organ into a human host would therefore create the opportunity for the transmission of PERVs, potentially enabling such viruses to evolve into human pathogens. Retrospective studies of patients who received heart valves from pigs identified the DNA of PERVs in some recipients. Therefore there is real concern that xenografts from pigs could provide a path for the transmission of novel viruses from animals to humans. Until this issue is resolved definitively, clinical trials of xenotransplantation are unlikely to move forward.

Transgenic Animals with Increased Disease Resistance

The ability to enhance disease resistance in animals holds enormous potential for the continuing field of animal biotechnology. Currently, numerous studies are being performed to induce disease resistance in a variety of animals. Some of the diseases being studied include mad cow disease, foot and mouth disease (FMD), porcine reproductive and respiratory syndrome (PRRS), and avian influenza viruses (AIVs).

Mad Cow Disease

Mad Cow Disease, or more formally bovine spongiform encephalopathy (BSE), is a specific type of a transmissable spongiform encephalopathy (TSE). TSEs are progressive, degenerative diseases of the brain, spinal cord, and central nervous system. They are also characterized by a long period of time between infection and detectable symptoms. The abnormal folding of the prion protein (PrP) is thought to cause TSEs. Abnormally folded PrPs can be transmitted and cause host PrPs to adopt abnormal configurations. Although the first TSE identified in cattle was in 1986 (BSE), TSEs have been documented in a variety of species (Wells *et al.*, 1987). The

human form of the disease is called Creutzfeldt–Jakob Disease (CJD), which was first characterized in 1920. However, scientists linked a new variant of CJD to BSE in 1996. Owing to the seriousness of the disease and the public health concerns, many studies are underway to induce resistance to these prion diseases. The primary method for inducing resistance is to silence the PRNP gene, which encodes for the normal PrP. These knock out studies, performed in cattle and mice, have shown that animals without the PrP are unable to produce and transmit the infectious form of the protein (Büeler *et al.*, 1993; Hirata *et al.*, 2004; Richt *et al.*, 2007).

Foot and Mouth Disease

FMD is a highly contagious disease that infects cloven-hoofed animals (those with divided hoofs). The pathogen responsible for FMD, foot and mouth disease virus (FMDV), is easily transmitted through direct contact, aerosols (air-borne), and ingestion. The virus also replicates rapidly once inside the host, and symptoms typically appear with 2–3 days. There are a variety of symptoms, but lesions on the tongue and feet characterize the virus. The virus is typically only lethal for younger animals. FMD poses enormous economic losses on the global livestock and trade industries. Not only does FMD wipe out herds of animals, many countries refuse to trade livestock with countries that experience FMD epidemics. Currently, vaccines provide the primary method to induce resistance to FMD. Researchers have recently created entirely synthetic vaccines to protect against FMD. However, vaccines remain problematic for eradicating FMD because of the fact there are more than 7 serotypes and more than 60 strains of the virus. This has sparked many studies that explore producing transgenic livestock that are resistant to FMD. Multiple studies have shown that RNAi is a viable antiviral strategy *in vitro* and *in vivo*, either through the use of small interfering RNAs (siRNAs) or short hairpin RNAs (shRNAs) (Haasnoot *et al.*, 2003; Grubman, 2005). Currently, no siRNA or shRNA transgenic livestock have been produced that are resistant to FMD, although many studies are being performed.

Porcine Reproductive and Respiratory Syndrome

PRRS is a viral disease that affects swine. PRRS is the largest economic hurdle the US swine industry faces, as the virus costs the industry approximately US$600 million each year. The two primary symptoms of PRRS are reproductive failure and respiratory complications for younger animals. The porcine reproductive and respiratory syndrome virus (PRRSV) is most often transmitted through direct contact, often appearing in high concentrations in semen, urine, feces, mammary secretions, and nasal secretions. Vaccines have been developed to help control the spread of PRRS, but the efficacy of the vaccines vary. The reason many vaccines are not effective is the virus's ability to generate a high degree of genetic diversity and its remarkable ability to evade host defenses. Owing to the unreliability of vaccines, other methods are being studied to control the disease. Some studies are focused on creating breeding programs that only breed swine with a high resistance to PRRS. Other studies are focused on creating transgenic pigs that are resistant through RNAi.

Avian Influenza Viruses

AIVs are a very diverse group of viruses that infect a wide variety of birds. However, because of their high rate of mutation, AIVs can also infect other species, such as humans. One example is the AIV strand H5N1. This is a fatal strand that can infect humans and many other species. These human health risks have sparked research into creating disease resistant fowls. Transgenic studies are at the forefront of this field. Transgenic chickens that are unable to transmit AIVs to other birds have recently been produced. This is a monumental achievement for genome editing and disease resistance.

Antimicrobials

The immune system of newborn piglets is immature, and thus they are susceptible to many bacterial infections, some of which cause diarrhea. These infections can also significantly reduce newborn survival rate. Although it is common to use antibiotic feed additives for newborns, this has led to a drastic increase in the number of antibiotic-resistant bacterial strains. This has required alternative approaches to prevent bacterial infections in piglets. Transgenic approaches offer great promise. Transgenic goats have been produced that make milk with the same concentration of lysozyme, the natural antimicrobial agent, as human breast milk (Brundige *et al.*, 2008). This milk was fed to piglets and it helped protect against *Escherichia coli* and improved gastrointestinal health. Transgenic cattle have also been produced that make human lysozyme and milk in their milk so that it is nutritionally similar to human breast milk.

Antimicrobial peptides (AMPs) exhibit another crossroad of transgenics and disease resistance. Cecropin B, the AMP that originates from the giant silk moth, has many antimicrobial effects. Many of these antimicrobial effects are against gram-negative bacteria. The gene encoding for cecropin B was transfected into catfish and the Asian medaka fish. Both transgenic fish breeds showed increased bacterial resistance to numerous pathogens.

Biotechnology Enhances and Advances Selective Breeding

Genetic Screening of Breeding Stock

Traditional animal breeding (TAB) exploited variations that existed within breeds and animal populations to bring about genetic improvement in traits of economic importance such as milk yield, growth traits, and egg numbers. TAB has been very successful over the years by utilizing records of the phenotype of an animal and a number of its relatives to estimate the likelihood that an animal will pass on its good traits to its offspring. An obvious example of the success of TAB is the doubling of dairy cow milk yields over the past 40 years (Oltenacu and Broom, 2010). However, for traits that are difficult to measure such as disease resistance, fertility, and feed efficiency, these traditional breeding methods have not been successful.

Genomics on the Dairy Farm: More Accuracy and Less Expense

Older pedigree tests used by the US Department of Agriculture (USDA) Animal Improvement Programs Laboratory were based on rating the genetic fitness of dairy cows by analyzing milk production records and assessing the quantity of certain cells in the cow's udder. Over the past 30 years, farmers and companies have selected for the best dairy cows using these tests. These tests can predict the genetic merit of a cow with 30% accuracy at birth. Breeders used the milk production records of a bull's relatives (mother, aunts, sisters, and daughters) to select good bulls to mate with their best dairy cows. Farmers with good bulls had to pay $50 000 for their bulls to be evaluated by breeding companies, and the breeding companies would create a detailed pedigree showing the bull's ancestry. However, in November 2006 the development of a new test based on genetic markers started. Led by Van Tassel, the USDA has determined approximately 38 000 genetic markers that aid in identifying cows that have the best genes for milk production and pass these genes to their offspring. A small single nucleotide polymorphism (SNP) chip can be used to track these 38 000 genetic markers in cows. This new genetic test can predict the genetic merit of a cow with 70% accuracy, compared to only 30% accuracy using traditional pedigree tests. Furthermore, instead of farmers paying US$50 000 for their bulls to be evaluated by breeding companies, it now costs only US$250.00 to genotype the bulls using this new genetic test.

The idea of using marker-assisted selection (MAS) to overcome the shortfalls of TAB has been around since 1923. MAS is the selection of traits of interest indirectly by selecting genetic markers associated with desired qualities, as opposed to traditional methods of finding desired qualities by observing phenotypic traits. Sax (1923) observed an association between seed color and seed weight and concluded that the gene controlling seed color must be linked to genes that control seed size. Thoday and Boam (1961) attempted to map and characterize polygenes affecting sternopleural chaeta number in *Drosophila melanogaster*. By estimating breeding values based on marker, pedigree and phenotypic information, MAS can bring genetic improvement in traits of animals where TAB alone has failed. In a French MAS program in dairy cattle, estimated breeding values (EBVs) using MAS for all traits considered were more reliable than EBVs estimated from classical selection methods (Guillaume *et al.*, 2008), demonstrating that MAS may lead to increases in genetic improvement as compared with traditional breeding methods.

Beginning in the late 1970's many molecular genetic markers were discovered and developed, including allozymes, restriction fragment length polymorphisms (RFLP), random amplified polymorphic DNA (RAPD), microsatellite DNA and SNPs. The ability to analyze these markers was developed over several decades and has made the mapping of quantitative trait loci (QTL) feasible on a large scale (Brumlop and Finckh, 2010). Out of these genetic markers, SNPs are currently the marker of choice because of their large numbers spaced across the genome. The decreasing cost and rapid progress in next-generation sequencing methods that employ massively parallel approaches in sequencing several hundred thousands to millions of reads simultaneously have led to the identification of many SNPs in livestock species. SNP arrays containing tens of thousands of SNPs distributed throughout the genome are now available for several livestock species (Table 2) and support the interrogation of hundreds of loci at a low cost.

Table 2 Available single nucleotide polymorphism (SNP) chips developed for some animal species

Species	*Identification*	*Provider*	*Number of SNPs*
Cat	Feline	Illumina	62 897
Horse	Equine	Illumina	65 157
Sheep	Ovine	Illumina	5 409
Cattle	BovineHD	Illumina	777 962
Cattle	BovineSNP50v2	Illumina	54 609
Cattle	BOS 1	Affymetrix	648 000
Sheep	OvineSNP50	Illumina	52 241
Cattle	BovineLD	Illumina	6 909
Pig	PorcineSNP60	Illumina	62 163
Dog	CanineHD	Illumina	173 662

Abbreviations: HD, high density; LD, low density.
Source: Reproduced from Eggen, A., 2012. The development and application of genomic selection as a new breeding paradigm. Animal Frontiers 2 (1), 10–15.

A disadvantage in the implementation of livestock MAS is that population-based, genome-wide association studies are unable to detect SNPs associated with a trait if the desired allele has a frequency below 5% or 1% (Brookfield, 2010). Additionally, MAS requires prior knowledge of markers that are associated with traits. Many markers are now known across the genomes of many livestock species, including cows, sheep, and pigs. Genomic selection, as initially proposed by Meuwissen *et al.* (2001), can use all these markers simultaneously to predict the genomic estimated breeding value (GEBV) for traits of animals without needing to know the location of genes in the genome.

Risks and Regulations

As with any foray into a new area of technology, there are several concerns about the use of animal biotechnology in agriculture and biomedical research. There is concern that food products derived from transgenic or cloned animals may pose risks to human health. There are also concerns about potential impacts of animal biotechnology on the environment and on animal welfare, as well as questions about whether the current regulatory structure is adequate to evaluate and control the risks associated with these technologies. Animals pose unique challenges compared to plants, as there is greater concern for the welfare of animals. Animal biotechnology, as well as its regulatory system, has been subjected to increasing attention and discussions among research scientists and the public. (About Bioscience; Animal Biotechnology: Science-Based Concerns, 2002; Cowan, 2010).

Human Health Concerns

Cloned and GE animals can be used as a source of tissues and organs for xenotransplantation and for production of biopharmaceuticals (Animal Biotechnology: Science-Based Concerns, 2002). Although xenotransplantation offers many

benefits, there are some risks including infection and rejection. Recipients of xenotransplantation risk direct exposure to recognized and unrecognized infectious agents such as prions, virus, or bacteria. Additionally, there is potential for future generations to become infected through vertical transmission (transmission of an agent from an individual to its offspring). Secondly, immunologic barriers associated with the use of xenografts are a concern, as in all allograft procedures. Although immune suppression therapies exist, hyperacute rejection is not always blocked (About Bioscience; Animal Biotechnology: Science-Based Concerns, 2002; Medscape).

The use of transgenic animals for the production of biopharmaceuticals for human health purposes has also raised several concerns. First, there is the potential risk of the generation of pathogenic viruses by recombination of vector sequences and related nonpathogenic viruses present in the same animal. The second concern is the possibility that surplus animals or their offspring inadvertently entering the food chain (Animal Biotechnology: Science-Based Concerns, 2002).

Food Safety Concerns

Concerns around all food and food products are based on the concept that they should be free of chemical or biological agents that can affect the safety of the food for the human or animal consumer (Animal Biotechnology: Science-Based Concerns, 2002; Kochhar and Evans, 2007). In 2001, the US producers agreed to keep food products from cloned animals or their offspring out of the food chain until the FDA could evaluate the risks. In 2008, the FDA released their report, which stated that meat and milk from cloned cattle, swine or goats or their offspring are as safe to eat as conventionally bred animals (Cowan, 2010, 2011; Bazer *et al.*, 2010).

Potential food safety concerns about products derived from GE animals, are mainly related to transgene expression. These transgenes could cause proteins to be present in food that could be allergenic, toxic, or have other antinutritional or/and other physiological effects. These concerns are considered a moderate-level concern of food safety and vary according to the gene product, the food product, and the consumer (Animal Biotechnology: Science-Based Concerns, 2002; Kochhar and Evans, 2007).

Animal Health and Welfare Concerns

The impact of genetic manipulation on animal health and welfare are of significant public interest. Ethical discussions are asking if these genetic manipulations can cause unnecessary stress in the animals (Animal Biotechnology: Science-Based Concerns, 2002; Cowan, 2010). For example, biomedical-use animals, specifically for those housed in sterile and isolated environments necessary for production of xenotransplantation tissues may experience stress and develop behavioral abnormalities. Rules are in place to try to alleviate any problems that might be caused by the pigs' environment (Animal Biotechnology: Science-Based Concerns, 2002). Continued evaluation of food safety, environmental safety, and animal welfare issues associated with animal biotechnology will be required as the field evolves.

Environmental Concerns

Several environmental concerns about GE animals are considered of high importance because both early identification and finding solutions to any problem are so difficult. The main concern is the possibility of GE animals entering natural environments (through release or escape) and disrupting ecosystems (Animal Biotechnology: Science-Based Concerns, 2002; Cowan, 2011).

For example, animals with high mobility and that have historic records of causing community damages, such as insects, shellfish, fish, and mice and rats, which can become feral easily and cause a high level of environmental concern. GloFish, a fluorescent red zebrafish, was the first transgenic animal commercially available in the US and a really popular aquarium item. Because this zebrafish is from southern Asia and cannot survive long in the cold US waters, it is believed that these GE zebrafish pose no risk to the environment. However, the AquAdvantage® Salmon (currently being evaluated) grow much faster than any wild salmon and, if released into the wild, could pose significant ecologic and genetic risks to native salmon stocks (Animal Biotechnology: Science-Based Concerns, 2002). This is why the company has proposed to sell only infertile female salmon eggs and which must be grown in inland tanks to reduce any risk of release into the wild. Furthermore, the cloning of extinct species, such as the woolly mammoth, is another focus of recent environmental concerns.

Regulation of Animal Biotechnology

United States

In the US most regulations are generally applied only to the products of biotechnology, not to the processes. It is focused on whether the products are safe for use, or 'generally recognized as safe' (GRAS) (Cowan, 2010, 2011; Bazer *et al.*, 2010). The US FDA and the USDA are primarily responsible for the regulation of animal biotechnology in the US. The FDA is responsible for the regulation of food safety issues for food animals produced by biotechnology, any environmental issues caused by these animals, and the regulation of drug safety. Concurrently, the USDA, with the animal and plant health inspection service (APHIS) and the food safety inspection service, regulates food products produced by animal biotechnology (Cowan, 2010, 2011; Cowan, 2010; Bazer *et al.*, 2010).

In 2009, the FDA released its final guidance statement regarding genetically engineered animals and products regulation. They defined GE animals as "those animals modified by recombinant DNA techniques, including the entire lineage of animals that contain the modification." These modifications are made with the purpose to 'alter the structure or function' of the animals involved. The process of registration and approval for use of new GE animals must follow the FDA's 'new animal drug' procedures. Currently, the FDA is working on the approval of the first GE animal to be used for human consumption. Although AquAdvantage® salmon were declared to pose no risk for human consumers in August 2010 (Cowan, 2010), the process began more than 10 years ago. Final approval will not be given for the salmon until studies of environmental issues are completed, possibly in 2013. However,

the FDA approved the first biopharmaceutical product produced by a transgenic animal (goats) in 2009. This was ATryn®, antithrombin III manufactured by GCC-Biotherapeutics.

When a product from animal biotechnology comes to the market, it is subject to FDA and APHIS labeling requirements. It is considered illegal to introduce food from a GE animal into the food supply without previous approval by FDA. For example, in food biotechnology, those products considered GRAS that are equivalent to food products that are already on the market, such as milk from cows receiving BST do not need to be labeled. However, those foods derived from GE animals that have altered genomes are not considered substantially equivalent and are required to be labeled. Attempts to create state laws for labeling of food produced by biotechnology have failed. Ethical questions regarding such labeling concern the right of the consumers to know the process by which food is produced. FDA is not allowed to consider those ethical questions. Its authority just covers safety issues (Cowan, 2011; Bazer *et al.*, 2010).

European Union and China

Outside the US, the regulation of animal biotechnology can differ a little. The European regulators, in contrast to the American, consider the biotechnology itself as a novel process that requires regulation (Bazer *et al.*, 2010). In the European Union, the European Medicines Agency regulates the approval of pharmaceuticals, whereas the European Food Safety Authority was set up in 2002 to be responsible for scientific risk assessment of food biotechnology. In addition, the European parliament and member states handle the risk management policy. The distribution of genetically modified organisms (GMOs) and GMOs used in food products are regulated by the Directive 2001/18/EC. This Directive requires notification before a product derived from genetic engineering comes to market. Furthermore, it is required that each product containing GMOs be labeled with the sentence: "This product contains genetically modified organisms" (Bazer *et al.*, 2010).

Animal biotechnology in China is regulated by three main agencies: the Ministry of Health, the Ministry of Science and Technology, and the Ministry of Agriculture. Although there is little formal legislation, there have been several statements concerning GMOs, whereas those statements formally apply to animals. Almost all enforcement involves the importation and production of plants instead of animals (CAST, 2010). In China, in contrast to Europe and US, there are no regulations related specifically to animal cloning. Instead, they have regulations regarding human cloning, leaving open all other research. The research in China is more lightly regulated and controlled than clinical and commercial applications. In 2004, an attempt to regulate animal welfare failed. Recently, new attempts have begun, but no regulations have been proposed (Bazer *et al.*, 2010).

Multimedia Annexes

PDF on Artificial Insemination

This PDF gives a basic overview of artificial insemination, beginning with semen collection and ending with the insemination procedure. It includes details such as the optimal thawing temperature for sperm and the accuracy of sperm-sorting procedures. It also details the advantages of disadvantages conferred by artificial insemination.

PDF on *In Vitro* Fertilization

This PDF gives a general overview of the IVF procedure, including the beginning steps of oocyte collection and ending with embryo culture. The PDF was designed for a laboratory course, therefore it includes exact reagents and volumes for the IVF procedure of cattle. It also includes information on embryo culture of other species. ICSI is also discussed.

PDF of the Food and Drug Authorities Final Guidelines on Genetically Engineered Animals

This is the document the FDA released in 2009 (and revised in 2011) that details their current policies on GE animals. These policies include information on introducing transgenic animals into the food supply, environmental concerns, record keeping, and many other topics. The guidelines are very thorough and detailed.

PDF on Molecular Markers

This file has a description of classical technologies involved in the development of molecular markers. Molecular markers discussed include RFLP markers, randomly-RAPD markers, amplified fragment length polymorphism (AFLP®) markers, microsatellite markers, SNP markers, sequence characterized amplified region (SCAR) markers, cleaved amplified polymorphic sequences, intersimple sequence repeat markers, and polymerase chain reaction-based sequence tagged site markers.

Glossary

Active ingredient Part of pesticide formulation that leads to biological effects of pesticides.
Characterization factors Characterization factors are used to quantitatively model the impact from each emission/consumed resource that comes from the life cycle inventory and are expressed as category indicatory results. The indicator of an impact category can be chosen anywhere along the impact pathway (midpoint or endpoint level). Characterization factors are usually calculated for continental and global scales.
Ecolabeling A voluntary method of environmental performance certification and labeling. An 'ecolabel' identifies the proven environmental preference of a product or service within a specific product or service category.
Endocrine disruptor Chemicals that at certain doses can interfere with the hormone system in mammals.
Hazard Inherent properties of a pesticide, which gives potential for adverse effects to humans or the environment during its production, use, or disposal, depending on the degree of exposure.
LC_{50}-concentration Statistically derived concentration of a pesticide expected to kill 50% of test organisms in a given population under set conditions.
Metabolite Intermediate or product resulting from metabolic processes.
Pesticide effect Result (change in biochemistry, morphology, physiology, growth, development, or lifespan of an organism which results in impairment of functional capacity or impairment of capacity to compensate for additional stress or increase in susceptibility to other environmental influences) from the exposure of humans, flora, and fauna to the (eco)toxicological active ingredients of pesticides.
Pesticide risk Combination of the fate of pesticides in the environment, which controls the potential exposure of humans, flora, and fauna to pesticides, and the (eco) toxicological properties of pesticides, which cause their potential effects on humans, flora, and fauna.
Risk assessment The process of defining the risk associated with a specified use pattern for a pesticide, usually expressed as a numerical probability. Risk quantification has three steps: identification of hazard, establishment of dose–response relationships in target individuals or populations, and exposure assessment.

Introduction

A particular challenge for humans of this century is to secure food for the growing world population accompanied by unprecedented urbanization and rural exodus rates. This challenge is exacerbated by the effects of global warming. As a consequence, risk management in food production systems urgently needs to be improved (Food and Agriculture Organization of the United Nations (FAO) Committee on World Food Security reports). Pesticides play a vital role in maintaining and enhancing agricultural efficiency and productivity, ensuring the quality of produce and availability of perfect produce throughout the year, and minimizing produce losses postharvest. A recent report concluded that without pesticides, crop yields would be halved and food prices would increase by 40% (Rickart, 2010).

The value of global crop protection products at the distributor level totaled US$44 Billion in 2011, which was an increase of 14.9% compared with 2010 (agribusiness consultancy reports). However, data on the global annual total volume of pesticides used are not available. It is suggested that the actual volumes have been declining during recent years in spite of the reported increasing market values (Agrow World Crop Protection News). It is, however, remarkable that the volumes of pesticides applied significantly increased for many years despite the fact that newer pesticides are applied at much lower rates. In Europe, the use of plant protection products is dominated by fungicides followed by herbicides. The volumes of insecticides applied are insignificant (European Commission statistical data). In the US, herbicides dominate the market, which are predominately applied in maize and soybean production systems. In Latin America, the sale of plant protection products has been continuously increasing since the 1990s, which is driven by growing soybean and sugarcane production as forage crops and also for biofuel. The trend for increasing use of pesticides in Asia is driven by the Japanese production systems, in particular the cultivation of rice, which accounted for approximately 40% of the Asian pesticide market value in 2003 (Agrow World Crop Protection News). The intensity of agricultural production is expected to further increase, motivated by the ever-increasing demand for food products from the growing world population and the improved average living standard in many parts of Asia. This will impact pesticide usage. It has to be noted, however, that pesticide volume alone is not a good indicator for risk as explained in the following paragraph.

The potential of pesticides to cause harm has long been recognized. Reports on undesirable environmental consequences of pesticide use are manifold and range from reduced pesticide efficacy due to the development of resistance to pesticides by plants and pests (Waltz, 2010; Palumbi, 2001) to the frequent detection of pesticides in European/US aquifers (Lapworth and Gooddy, 2006; Moncrieff *et al.*, 2008; Denver *et al.*, 2010; Vryzas *et al.*, 2012). Pesticides can potentially cause undesirable adverse side effects on nontarget organisms, humans, and the environment (soils, surface, and groundwater resources) because pesticides are toxic by design and are deliberately released into the environment. Pesticide risk is a combination of the (eco)toxicological properties and the potential exposure of humans, flora, and fauna to the active ingredients – thus, risk depends not only on how toxic a chemical is, but also on how it is actually used, where it is used, how much of it is used, and how often it is used. The fate of pesticides in the environment is crucial for the risks associated with pesticide usage. The (eco)toxicological properties determine the hazard of a pesticide. Effects of hazardous substances are quantified under controlled conditions in laboratory or field experiments by measuring how much of an individual active substance is required to kill or affect test organisms. There is a growing awareness of the environmental risks associated with pesticide use, and an emergent societal pressure to reduce these risks and better manage the impacts of pesticides on the environment.

This article gives a general introduction to the fate of pesticides in the environment, summarizes the risks associated with the production, use, and disposal of pesticides, and provides an overview on current strategies and tools to minimize the risks associated with the use of pesticides. It also points out new directions in the efforts of reducing the risk associated with pesticide use.

Pesticides in the Environment

The International Union of Pure and Applied Chemistry defined pesticide risk as "the probability of any defined hazard occurring from exposure to a pesticide under specific conditions. Risk is a function of the likelihood of exposure and the likelihood to harm biological or other systems" (Holland, 1996). In other words, pesticide risk is a combination of the fate of pesticides in the environment, which controls the potential exposure of humans, flora, and fauna to pesticides, and the (eco)toxicological properties of pesticides, which cause their potential effects on humans, flora, and fauna.

This section provides an overview on both these aspects. The first part of this Section Pesticide Fate is dedicated to the fate of pesticides in the environment, which determines the potential exposure of humans, flora, and fauna to the active substances of pesticides. The second part of the Section Pesticide Effects is dedicated to the potential adverse effects pesticides can have on humans, flora, and fauna. Both the sections conclude with a paragraph in the respective section describing the tools and models that are used to assess pesticide risks.

Pesticide Fate

In this section, the entire life cycle of pesticides is considered, from the manufacturing of the active substances to the formulation of the pesticide product, to the use of the products and the disposal of residual pesticides and containers by the end user.

Pesticide fate during manufacturing and transport

Generally, pesticides are produced in two phases: the chemical synthesis of the active ingredients (manufacturing) is followed by mixing/diluting of the active ingredients with carrier substrates surfactants or other active ingredients into the final pesticide product (formulation). During the manufacturing, formulation, packaging, and distribution of pesticides the potential human exposure to excessive amounts of pesticides is the highest in the entire lifetime of a pesticide. Many studies have analyzed the potential exposure ways and related acute and chronic health risks for workers including neurological, circulatory, and reproductive problems (Sailaja *et al.*, 2006; Bhalli *et al.*, 2006). In the past, not only improper handling of pesticides in manufacturing, formulating, and packaging companies but also pesticide spills during transport have led to accidents worldwide (Cox, 1993). Residents, emergency workers, and the environment are then at the risk of being exposed to toxic emissions often in a cocktail of initially unknown compounds. In 2007, the World Bank Group published a document entitled 'Environmental, health, and safety guidelines for pesticide manufacturing, formulation, and packaging' (World Bank Group, International Finance Corporation Guidelines). These guidelines cover the potential environmental risks, occupational and community health and safety. Performance indicators and monitoring guidelines recommended for air emissions, wastewater, and waste products are provided.

Pesticide fate during and after application

What happens to pesticides following application on the farm has been intensively investigated since the publication of 'Silent Spring' by Rachel Carson (1962). Basically, the fate of pesticides after application is governed by three processes: the partitioning between the different environmental compartments, such as air, soil, water, and plant; the transport in an environmental compartment; and transformation processes. A schematic diagram of the most relevant processes during and after pesticide application is presented in **Figure 1**. Various factors determine the fate and behavior of pesticides including the properties of the active ingredient as well as the other ingredients of the formulated pesticide product, biological, chemical, and physical soil properties; and other environmental factors including climate, weather during application, topography, application techniques, etc. Pesticide properties that are beneficial to the environment may be suboptimal from an economical point of view, for example, a desirable pesticide property from an environmental point of view is a short persistence. However, a longer-lasting pesticide residue might be economically advantageous due to the longer effectiveness of the pesticide as long as the residues are not impacting the crops following in a crop rotation scheme.

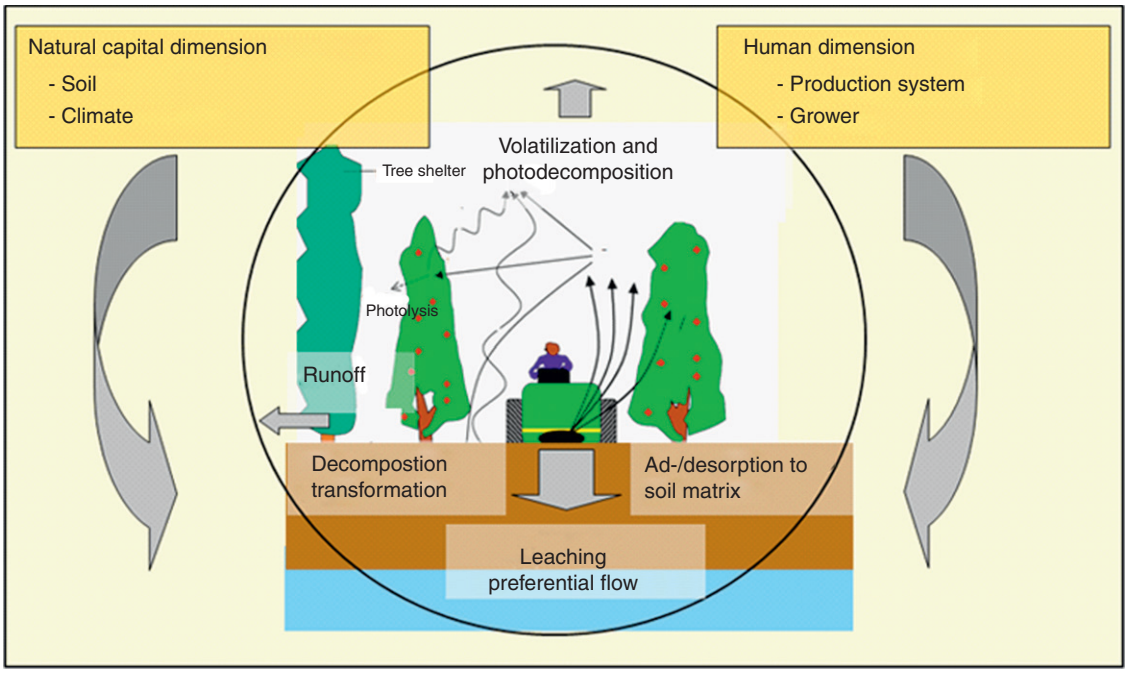

Figure 1 Pesticide fate in the environment after its application.

A thorough understanding of the factors affecting pesticide behavior in the different environmental compartments is necessary to maximize the agricultural benefits and minimize adverse environmental impacts of pesticides. Various review papers have been published on related topics (Gevao *et al.*, 2000; Sarmah *et al.*, 2004; Aislabie and Lloyd-Jones, 1995; Wauchope *et al.*, 2002; Wauchope, 1978; Flury, 1996; Kookana *et al.*, 1998; Beulke *et al.*, 2000; Reichenberger *et al.*, 2007). During the actual application of pesticides, workers and residents can be directly exposed to pesticides through spray drift and volatilization of pesticides, which are influenced by the application techniques, wind speed, humidity, and temperature during application. Exposure of workers is particularly important in greenhouses, because these are relatively closed systems (van Eerdt *et al.*, 2012). Other undesirable losses during and after the application include losses to nontarget areas in the field, such as usually the soil and transport of pesticides into ground and surface water resources. Once the pesticides are in the soil, pesticide–soil–soil water interactions govern their sorption, transformation, degradation, and transport through the soil. Topics that initiated many research activities in this area include the fate of aged residues and metabolites in soils (Ahmad *et al.*, 2004; Gevao *et al.*, 2000; Anhalt *et al.*, 2000) and the impact of pesticide formulation on the behavior of active ingredients (Tsui and Chu, 2003; Contardo-Jara *et al.*, 2009; Evans *et al.*, 1998; Wauchope *et al.*, 1990; Hilz and Vermeer, 2013). A relatively new focus of concern is the environmental fate of nanopesticides, which has been recently reviewed by Kah *et al.* (2013). In the context of pesticides, nanotechnology is used (1) to formulate and deliver active ingredients and (2) to offer new active ingredients, such as nanosilver. Nanoformulations of pesticides are expected to significantly impact the fate of active ingredients; however, the environmental fate of new nanoactive ingredients is poorly understood (Kah *et al.*, 2013).

Among the contamination of air, water, and soil by pesticides, water contamination is still the biggest concern. It originates from two different sources: point and nonpoint sources (Müller *et al.*, 2002). In the literature, this terminology is not used consistently (Leon *et al.*, 2001; Mohaupt *et al.*, 2000; Reichenberger *et al.*, 2007). In accordance with Müller *et al.* (2002), the authors define point pollution as the discharge of a discrete identifiable source like a waste pipe. Therefore, the pesticide load, which is contributed to a stream by a wastewater treatment plant system, is referred to as point source pollution. These loads result from disposal of pesticides, filling and cleaning of spraying equipment on farmyards during dry weather periods, washing off pesticide residues from impervious areas (farmyards, streets, roofs, etc.) during storm events and discharge from greenhouses (EFSA Panel on Plant Protection Products and their Residues (PPR), 2012a). Nonpoint sources or diffuse inputs result from the agricultural application in the field and include processes like soil surface runoff, interflow, preferential flow, drainage, atmospheric deposition, and spray drift (**Figure 2**).

Pesticide fate during disposal

In many countries, no guidelines or structures for pesticide users to dispose of remainders of hazardous products and empty pesticide containers exist. Owing to the lack of proper waste management systems for pesticide containers and residual pesticides, these are often inappropriately discarded, such as in uncontrolled landfills or by uncontrolled burning. These procedures may contaminate soil and water, and expose humans, animals, and plants to pesticide products and their metabolites or toxic emissions. Case studies in Germany reported that the cleaning of the sprayer and tank used for

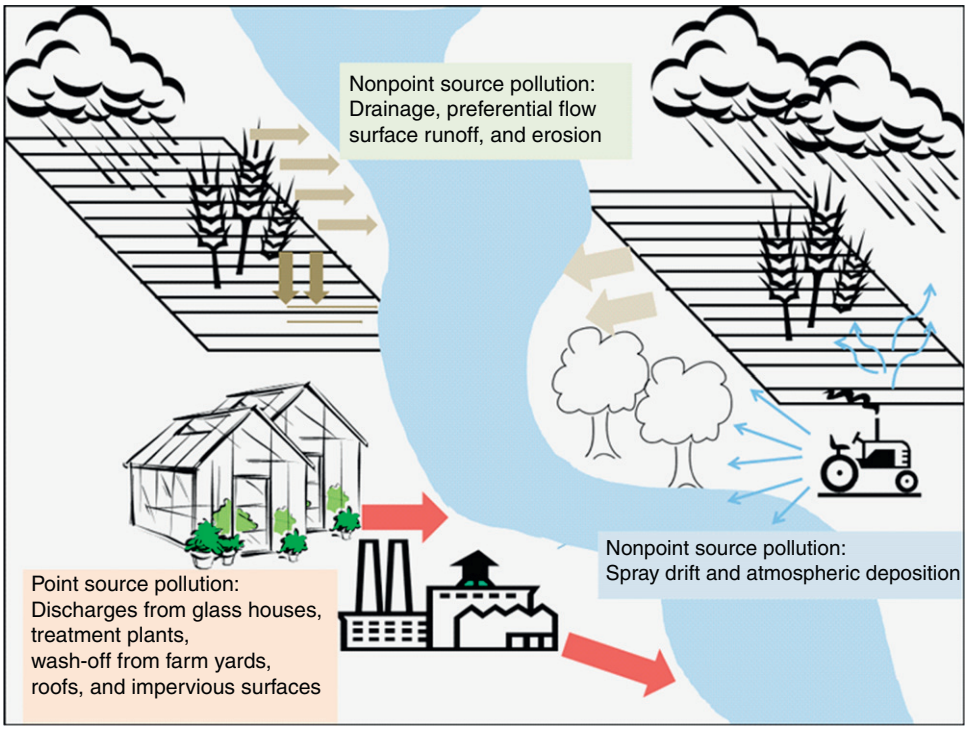

Figure 2 Schematic drawing showing pathways for point and nonpoint source pesticide pollution to surface water resources.

pesticide applications and the inappropriate treatment of pesticide residues left in the tank after application contributed the majority of the pesticide residues detected in surface water resources, which entered the streams through wastewater treatment plant systems (Fischer, 1996; Müller *et al.*, 2002).

On a larger scale, developed countries export unwanted pesticides, for example, pesticides that are no longer permitted, to other, often developing countries. The FAO is dealing with the legacy of problems related to this common practice ('FAO Information'). For example, the FAO currently has a program entitled 'The clean up of obsolete pesticides, pesticides management, and sustainable pest management,' which is part of the European Commission project on 'Capacity Building related to Multilateral Environmental Agreements in African, Caribbean, and Pacific countries' (FAO Information on Multilateral Environmental Agreements).

Pesticide fate models

Pesticide fate models are needed to interpret the observed pesticide distribution in the environment and to improve our understanding of the fundamental processes leading to the contamination of air, water, and soil. Pesticide fate models are also needed to describe human exposure. Human exposure to pesticides can be via dietary, occupational, and environmental exposures. Dietary human exposure to pesticides present in fruits and vegetables is an important aspect of food safety in Europe, the USA, and Australasia. It is the most relevant aspect of human exposure to pesticides. To estimate the dietary human exposure to pesticides different modeling approaches have been developed including point estimates, deterministic, and probabilistic modeling (Suhre, 2000; FAO/WHO, 2001; FAO/WHO, 1997). The scope of this section, however, is limited to the distribution of pesticides in different environmental compartments and environmental pesticide fate models.

A huge number of pesticide fate models has been developed since the 1980s, including PELMO (Klein *et al.*, 2000), CREAMS (Knisel, 1980), Opus (Smith, 1992), MACRO (Jarvis, 1994), HYDRUS-2D (Šimunek *et al.*, 1996), LEACHM (Wagenet and Hutson, 1987), PEARL (Tiktak *et al.*, 1998; Tiktak *et al.*, 2012), RZWQM (Ma *et al.*, 2004), and EuroPEARL (Tiktak *et al.*, 2004). Comprehensive reviews of models for pesticide transport in soils are given, *inter alia*, by Jury and Ghodrati (1989); Cohen *et al.* (1995); Tiktak (2000); Simunek *et al.* (2003); Nolan *et al.* (2005); and Dubus and Surdyk (2006). The majority of these models is deterministic, but some stochastic models have also been proposed (Lindahl *et al.*, 2005; Zacharias *et al.*, 1999; Jury and Roth, 1990; Heuvelink *et al.*, 2010). Deterministic models assume that a given set of initial and boundary conditions leads to a single outcome due to certain processes that can be described mathematically, whereas stochastic models take into consideration the spatial and temporal heterogeneities in soil properties and processes. The outcome of any one realization is considered to be uncertain. A large number of sample realizations lead to the definition of the probability density function for the underlying process.

Regardless of the model complexity, all models simplify reality to a certain degree and the algorithms implemented need to be validated (Arenstein *et al.*, 1993; Armstrong *et al.*, 1996; Clemente *et al.*, 1998; Thorsen *et al.*, 1998). Generally, pesticide fate models need to be calibrated for a site before any attempts of model validation (Dubus *et al.*, 2002; Tiktak, 2000). In spite of extensive efforts in pesticide fate modeling

for approximately 35 years, accurate predictions of pesticide behavior are still a daunting task partly because of the vast spatial variability of environmental parameters affecting pesticide fate (Coquet, 2002; Bundt *et al.*, 2001; Ghafoor *et al.*, 2012; Ghafoor *et al.*, 2011), and also due to existing knowledge gaps and lack of understanding of the process with regard to, *inter alia*, preferential flow, impact of soil structure, and transitional soil properties, such as soil water repellency on fluxes and sorption processes, impact factors controlling transformation and degradation in the subsoil, etc. (Duwig *et al.*, 2008; Prado *et al.*, 2006; Boesten, 2000; Täumer *et al.*, 2006; Jury *et al.*, 2011; Vanclooster *et al.*, 2000).

Most of the pesticide fate models focus on a single environmental compartment, for example, groundwater, and aim to predict environmental concentrations depending on climate, soil, and other boundary conditions. Multimedia fate models as developed by Mackay and Paterson (1991) target mainly persistent pesticides and their transfer between the different environmental compartments on a global scale. There is a need to extend these into models applicable and meaningful for the local scale.

Pesticide Effects

In this section, some examples of pesticide effects resulting from the exposure of humans, flora, and fauna to the (eco) toxicological active ingredients of pesticides are provided. First of all, it has to be noted that chronic and acute effects of pesticides can be distinguished. Chronic toxicity is defined as the "capacity for a pesticide to produce injury following chronic exposure or to produce effects which persist whether or not they occur immediately on exposure or are delayed" (Holland, 1996). In contrast, acute toxicity is the "ability of a substance to cause adverse effects within a short period following dosing or exposure" (Holland, 1996). Furthermore, adverse effects need further specification. In the simplest case, lethal and sublethal effects can be distinguished (Desneux *et al.*, 2007). Duffus (1993) and Nordberg *et al.* (2007) compiled comprehensive overviews on different toxicological terms.

For example, pesticide residues in water resources are discussed as one of the potential factors for fish and amphibian deformations that have been observed globally (Hayes *et al.*, 2010). Negative effect of pesticides on pollinators (Gill *et al.*, 2012) and biodiversity in soils (Bhat, 2012) have been reported. Moreover, pesticide exposure is discussed as a potential trigger for cancer (Alavanja and Bonner, 2012; Ventura *et al.*, 2012; Alexander *et al.*, 2012; Koutros *et al.*, 2013); neuroanomalies among children have been explained by pesticide exposure (Rosas and Eskenazi, 2008), and some pesticides are suspected to act as endocrine disruptors (Mnif *et al.*, 2011). Health issues related to pesticide usage are associated with significant costs. A recent paper estimated that in the US the annual costs linked to pesticide exposures were approximately US$200 million based on the data from emergency department visits, hospitalizations, and for deaths (Langley and Mort, 2012). It has been commonly accepted that pesticide residues in produce are an issue of concern and have led some supermarket chains to devise their own regulations and maximum acceptable threshold values (Lang and Barling, 2007).

Generally, the (eco)toxicological properties of the active ingredients determine the hazard of pesticides. Effects of hazardous substances are quantified under controlled conditions in a laboratory, semifield or field experiments by measuring how much of an individual active substance is required to kill or affect test organisms. The various types of experiments are explained in more detail in the section on registration of pesticides in this article. Problems associated with these tests are that normally the experiments are conducted under controlled conditions, synergy effects of exposure to multiple chemicals are excluded, and effects of metabolites are often not considered. Moreover, the vulnerability of adults and children are very different, and for ecotoxicological tests, the choice of appropriate test organisms is crucial. Pesticide effect models are used to address these problems.

Pesticide effect models

As it is impossible to test all combinations of organism, substance, environmental, and exposure conditions with experiments, models are crucial for the quantification of (eco)toxic effects for the risk assessment of pesticides. Many different pesticide effect models have been developed including, for example, Mastep (Van den Brink *et al.*, 2007), PERPEST (van Nes and van den Brink, 2003), TDM (Ashauer *et al.*, 2007), and General Unified Threshold model for Survival (GUTS) (Jager *et al.*, 2011). The simplest models are statistical (e.g., LC_{50} concentration, lowest observed effect concentration) and physical (e.g., *Daphnia magna*, microcosm) models, which do not incorporate any systematic understanding of the system of interest (EFSA Panel on Plant Protection Products and their Residues (PPR), 2013). In contrast, mechanistic toxicity models make explicit assumptions about the dynamic processes underlying the toxic response. This procedure allows extrapolating results to different exposure and environmental conditions. Mechanistic models have been developed for individuals, populations, and ecosystems (Preuss *et al.*, 2009; Grimm *et al.*, 2009; Jager *et al.*, 2011; Thorbek *et al.*, 2009). Population models aim at extrapolating lethal and sublethal effect from the individual to the population level (Preuss *et al.*, 2010). Ecosystem models allow the risk characterization within ecosystems, integrating biotic interactions (Park *et al.*, 2008; Hommen *et al.*, 1993).

More realistic are the process-based toxicity models, which are dynamic and take into account fluctuating concentrations and pulses of pesticides. They simulate the processes leading to toxicity at the level of organisms over time (Ashauer and Escher, 2010). Usually, this model type predicts survival of individual organisms (Jager *et al.*, 2011) but is now also applied to sublethal endpoints (Ashauer and Brown, 2013). For example, on the level of an individual, this model type simulates sublethal effects over time, based on uptake of the toxicant and damage and repair processes within the organism. This generation of pesticide effect models is labeled toxicokinetic–toxicodynamic (TK–TD) models (Jager *et al.*, 2011). These models provide a conceptual framework to better understand the causes for variability in sensitivity between different species to the same compound as well as causes for

different toxicity of different compounds to the same species. An example of a TK–TD model is the GUTS (Jager *et al.*, 2011). In addition, models taking into account the effect of mixtures of pesticides have been developed and different methodologies have been proposed (de Zwart and Posthuma, 2005).

Strategies to Reduce Pesticide Risks

The most important approaches to reduce pesticide risks include:

- regulate and control pesticide production and use,
- promote safe pesticide use,
- apply pesticide risk assessment tools to optimize pest management,
- apply agricultural management strategies, such as to
  - apply integrated pest management (IPM) practices,
  - convert conventional agricultural production into certified organic production systems, and
  - enhance resilience of agricultural production systems,
- enhance pesticide life cycle stewardship (LCS), such as to
  - conduct life cycle assessment (LCA) of pesticides and
  - promote ecolabeling of products.

Regulation and Control of Pesticides: Registration

Pesticides need to be registered by competent authorities before they can be sold and used. Once registered, its use must be consistent with the approved directions for use on the pesticide's label. As such, pesticide registration is an important mechanism to keep the most toxic substances of the market and inhibit manufacturing of these substances. In the European Union (EU), pesticide regulation (Regulation 1107/2009/EC) offers a framework for the registration of pesticides. According to its preamble, it is required that "pesticides, when properly applied for the purpose intended, are sufficiently effective and have no unacceptable effect on plants or plant products, no unacceptable influence on the environment in general and, in particular, no harmful effect on human or animal health or groundwater."

Pesticide registration is increasingly based on scientifically sound, harmonized, and transparent environmental risk assessment (ERA) procedures. Responsible authorities for developing such methods are – among others – the European Food Safety Authority (EFSA) in the EU and the Environmental Protection Agency (EPA) in the US. For the development of robust and scientifically sound ERA procedures, it is crucial to define clear protection goals. However, protection goals are only broadly defined in EU and US legislation. Therefore, a translation into the so-called 'specific protection goals' is necessary. Specific protection goals define what to protect, where to protect it, and over what time period (EFSA Panel on Plant Protection Products and their Residues (PPR), 2010). This definition is in line with US-EPA's definition of 'generic assessment endpoints.' An assessment endpoint is defined as an explicit expression of the environmental value to be protected, operationally defined as ecological entity and its attributes (US EPA, 2003). The process of developing specific protection goals is part of the problem formulation in the ERA framework (Figure 3). On the basis of these specific protection goals, competent authorities develop guidance to be used by risk assessors. Risk managers finally base the granting of marketing authorizations for individual pesticides on the work done by risk assessors.

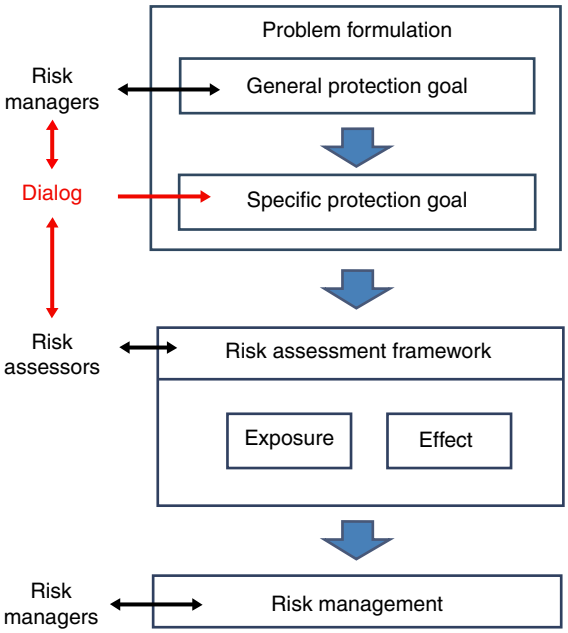

Figure 3 Relation between problem formulation, protection goals, risk assessment framework, and risk management in the process of pesticide authorization (EFSA Panel on Plant Protection Products and their Residues (PPR), 2010).

Tiered approaches are nowadays the basis of environmental risk-assessment schemes that support the registration of pesticides (Brock *et al.*, 2010; EFSA Panel on Plant Protection Products and their Residues (PPR), 2013; EFSA Panel on Plant Protection Products and their Residues (PPR), 2012b; Tiktak *et al.*, 2012; Tiktak *et al.*, 2013). A tier is defined as a complete exposure or effect assessment resulting in an appropriate endpoint (e.g., the concentration in surface water). The concept of tiered approaches is to start with a simple conservative assessment and only to do additional more complex work if necessary (so implying a cost-effective procedure both for industry and regulatory agencies). The general principles of tiered approaches are (Boesten *et al.*, 2007):

1. lower tiers are more conservative than higher tiers,
2. higher tiers are more realistic than lower tiers,
3. lower tiers usually require less effort than higher tiers,
4. in each tier, all available relevant scientific information is used,
5. all tiers aim at the same specific protection goal.

In short, the tiered exposure assessment needs to be internally consistent and cost-effective and needs to address the problem with higher accuracy and precision when going from lower to higher tiers. These principles permit moving directly to higher tiers without performing the assessments for all lower tiers.

An example of a tiered assessment scheme is presented in Figure 4. This example focuses on effects on aquatic organisms

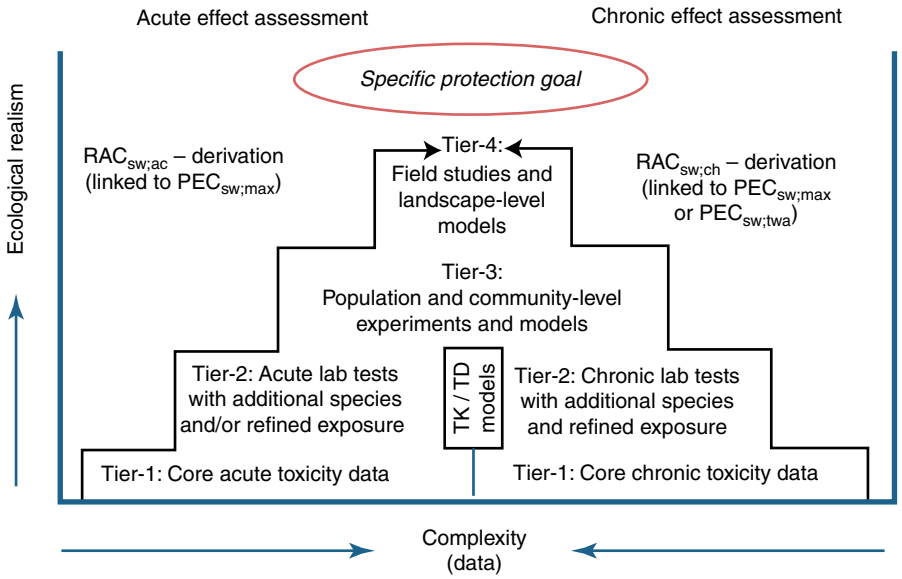

Figure 4 Schematic representation of the tiered approach within the acute (left part) and chronic (right part) effect assessment for pesticides. For each pesticide, both the acute and chronic effects/risks have to be assessed. Each tier results in a regulatory acceptable concentration (RAC) that needs to be compared with a relevant exposure concentration to identify whether a risk is present. PEC, predicted environmental concentration; TX/TD, toxicokinetic/toxicodynamic. Reproduced from EFSA Panel on Plant Protection Products and their Residues (PPR), 2013. Guidance on tiered risk assessment for plant protection products for aquatic organisms in edge-of-field surface waters. European Food Safety Authority Journal 11, 3290–3558. Available at: www.efsa.europa.eu/efsajournal (accessed 06.02.14). doi: 10.2903/j.efsa.2013.3290.

living in the water column of edge-of-field surface waters (EFSA Panel on Plant Protection Products and their Residues (PPR), 2013). The endpoint for each tier is a RAC. The diagram contains two distinct effect assessment schemes, that is, one for acute effects and one for chronic effects. Note, however, that both the schemes aim at the same specific protection goal (which in most cases have only negligible effects at the population level). Tier 1 is a single-species laboratory toxicity test using only core toxicity data. At tier 2, additional single-species tests are added allowing the derivation of more sophisticated and more realistic statistical measures to describe the potential effects. At tier 3, population-level experiments are carried out under semifield conditions (the so-called mesocosms). This allows direct quantification of effects at the population level with realistic pesticide use strategies, which is of course closer to the intended specific protection goal and therefore more realistic. It is, however, also more laborious than single-species experiments. At tier 4, field studies are carried out or population-level models are applied at the landscape level. The latter allows direct quantification of worst-case conditions (e.g., 90th percentiles of effect levels) as is done in the fate part of the risk assessment (Section Regulatory Risk Assessment Models). Although population-level effect models at the landscape level exist (Schmolke *et al.*, 2010), they are currently not operational in the regulatory context.

The RACs obtained in the effect assessment need to be compared with relevant exposure concentrations to identify whether a risk is present. In the acute effect assessment, the RAC is always compared with the concentration directly after exposure (this is usually also the maximum concentration in time). For the chronic effect assessment, some sort of time-weighted average exposure concentration may be used (EFSA Panel on Plant Protection Products and their Residues (PPR), 2013).

So pesticide registration is primarily based on prospective risk assessment. A new element of the EU-Pesticides Regulation is, however, that it provides the possibility to reject pesticides on the basis of intrinsic properties alone (the so-called hazard-based cutoff criteria). This means that pesticides that fail one of the hazard-based cutoff criteria will not be further evaluated even when it is clear that potential exposure is negligible. Cutoff criteria are given for 'persistence, bioaccumulation, and toxicity criteria.' Pesticides can neither be registered if they are mutagenic, carcinogenic, or toxic for reproduction, nor considered to have endocrine-disrupting properties. However, the definitions of some of the cutoff criteria, such as endocrine disruptor, are not yet finalized (Williams, 2011).

Regulatory risk assessment models

Some of the exposure models described under the Section Pesticide fate models are used to support the registration process above. For regulatory purposes, however, the models are used in combination with standardized scenarios and user-friendly software shells. A scenario consists of a combination of soil, climate, and crop parameters to be used in modeling. Standardized scenarios are needed because they increase the uniformity of the regulatory evaluation process by minimizing the influence of the methodology applied and of the person that performs the predicted environmental concentration (PEC) calculation and because they make exposure assessments and their interpretation easier for regulators and industry (Boesten, 2000; Vanclooster *et al.*, 2004; Tiktak *et al.*, 2013). Usually, realistic worst-case scenarios are assumed, and the simulations provide estimates of the exposure

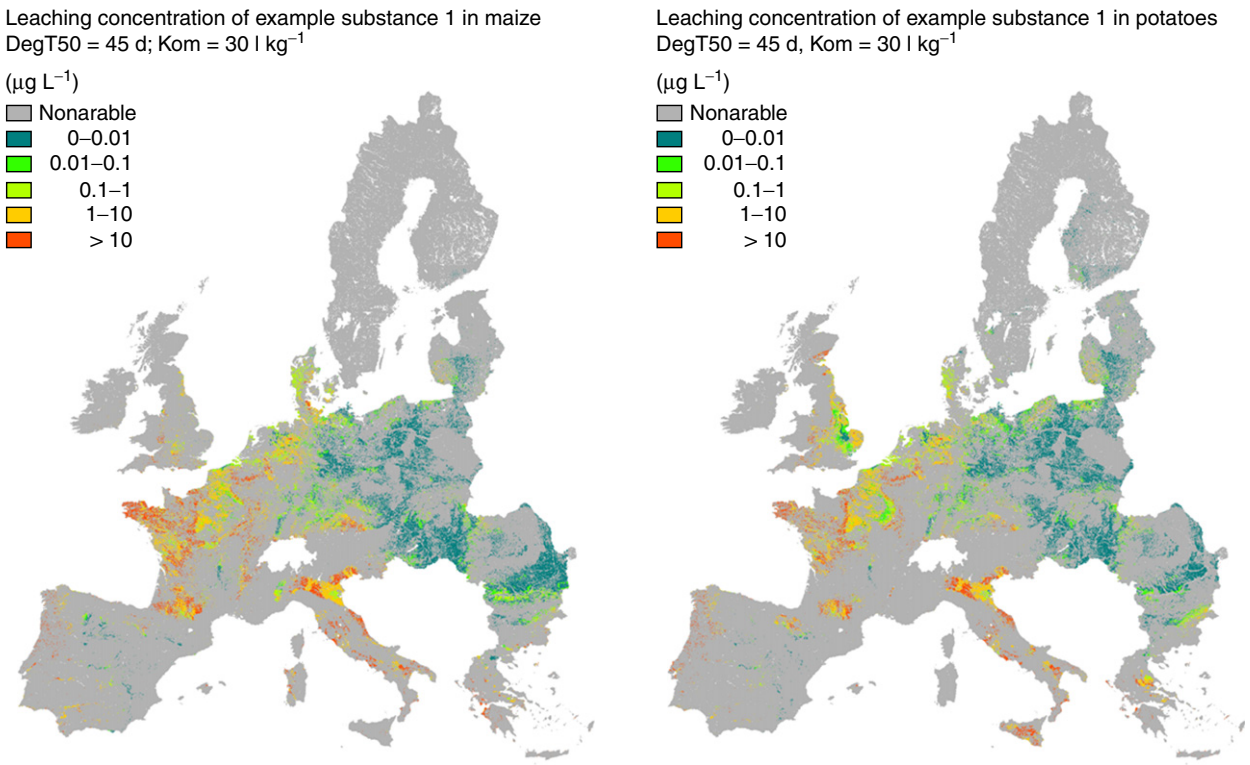

Figure 5 Leaching concentration of an example substance in two different crops, that is, corn (left) and potatoes (right). As the protection goal is the 90th percentile of the leaching concentration in a specific crop, percentiles are only calculated for the area where this crop is present. This implies that the 90th percentile is crop dependent. Calculations are done with a metamodel of EuroPEARL (Tiktak *et al.*, 2006).

concentration that are close to the exposure assessment goal set by risk managers. Examples of regulatory models include MACRO (Larsbo and Jarvis, 2003), PEARL (Leistra *et al.*, 2000), PELMO (Klein, 2011), PRZM (Carsel *et al.*, 1985), TOXSWA (Adriaanse, 1996, 1997), and PERSAM (Tiktak *et al.*, 2013).

In Europe, the development of these models has been coordinated by the forum for the coordination of pesticide fate models and their use (FOCUS). FOCUS has published general guidance documents and reports on the use of pesticide fate and transport models for predicting environmental concentrations in groundwater (FOCUS, 2000; FOCUS, 2009) and surface water (FOCUS, 2001). Recently, this task has been taken over by the EFSA. Their first guidance considered the assessment of exposure of soil organisms (EFSA Panel on Plant Protection Products and their Residues (PPR), 2012b).

As already mentioned, the exposure scenarios must represent the protection goal set by risk managers. In the leaching assessment of pesticides to groundwater, the protection goal was defined to be the 90th percentile of PEC values within the agricultural area of use of the pesticide in each of the nine climatic zones across the EU (FOCUS, 2009). For the exposure assessment of soil organisms, the 90th percentile exposure concentration was used as well, but the number of zones was limited to three (EFSA Panel on Plant Protection Products and their Residues (PPR), 2012b).

EFSA Panel on Plant Protection Products and their Residues (PPR), 2012b developed a statistical approach to find such scenarios. In their approach, scenario development began with the simulation of the concentration distribution in the entire area of use of a pesticide by means of a simple spatially distributed model. In a following step, the scenario was directly selected from the map of the simulated concentration. An alternative to the use of a limited number of worst-case scenarios is to use the spatially distributed model directly. In this approach, maps of the exposure concentration are created for the entire area and the 90th percentile is directly obtained from the frequency distribution of the so-obtained maps (**Figure 5**). Examples of the spatially distributed regulatory models are GeoPEARL (Tiktak *et al.*, 2003) and EuroPEARL (Tiktak *et al.*, 2004).

Enhance Safe and Effective Pesticide Use

Safe pesticide use includes both reducing the health risk for the user and the community and also minimizing the potential environmental aspects of pesticide applications. To enhance safe pesticide use, the general public has to be aware of the risks and problems associated with applying pesticides. Thus, the responsibility for safe pesticide use starts before the user with the registration of products, marketing, and advertising of pesticides. If pesticide products were only available in specialized shops like prescription pharmaceuticals, their distribution and usage would be easier to control. The wearing of personal protective equipment (PPE) during pesticide application as well as the maintenance of PPE should be part of a responsible advertising campaign. The implementation of

administrative controls, such as restricting pesticide usage to registered users and compulsory spray diaries for farmers would improve the safety of pesticide use. Spray diary records from individual pesticide users have been recognized as the best baseline for a comprehensive system for pesticide use recording (Manktelow *et al.*, 2005). In addition, improving the training and education of pesticide users are crucial. Related activities are already in place in many countries with handbooks on safe pesticide use (Marer, 2000), and initiatives like 'safe use' by CropLife International, a federation representing the plant science industry. For example, in New Zealand, a nonprofit trust aims to promote the safe, responsible, and effective use of agrichemicals by offering 'GROWSAFE' training courses that cover the knowledge and practices required for safe, responsible, and effective use of agrichemicals. The situation in developing countries is challenging due to the high level of illiteracy and low education levels, which impede training of pesticide users (Ekström and Ekbom, 2011). Some potential strategies to enhance the safe and effective use of pesticides are summarized in **Table 1**.

Application of Pesticide Risk Assessment Tools to Optimize Pest Management

To evaluate the risks associated with pesticide applications, more than 100 different pesticide risk assessment tools have been developed (Surgan *et al.*, 2010). Many comprehensive reviews, comparisons of different tools, often in the form of case studies, have been published (Labite *et al.*, 2011; Reus *et al.*, 2002; Kookana *et al.*, 2007; Stenrød *et al.*, 2008; Bockstaller and Girardin, 2003; Maud *et al.*, 2001; Dubus and Surdyk, 2006). In general, pesticide risk assessment tools are knowledge-based tools designed to support pesticide users and regulators in their decisions regarding the selection and regulation of the use of pesticides with the aim to minimize associated risks. More specifically, applications of pesticide risk assessment tools include:

- selection of lower risk pesticides,
- selection of pesticides that better match local conditions,
- optimization of pest management strategies as part of IPM systems,
- design pesticide reduction plans at the national and EU level, and
- monitoring the progress of pesticide reduction plans at the national scale.

This broad range of applications is reflected in the wide range of complexity of different pesticide risk assessment tools. All tools have something in common: they combine a range of data into a single or composite index for the comparative evaluation of the risk associated with a specific pesticide. Aggregation of data into an index ranges from simple scoring to fuzzy logic systems (van der Werf and Zimmer, 1998), which integrate both qualitative and quantitative information (Labite *et al.*, 2011). Commonly, the risks assessed are those related to human health, aquatic and terrestrial biota, birds, or the risk to contaminate environmental compartments. As mentioned earlier, the potential for pesticides to result in environmental damage and to adversely affect humans, flora, and fauna is extremely site-specific and is not solely dependent on the (eco) toxicological properties of the pesticide. In addition, application rates and timing are crucial to the fate of pesticides. Thus, more complex tools integrate risks related to pesticide use within a crop protection context at the local scale (Reus

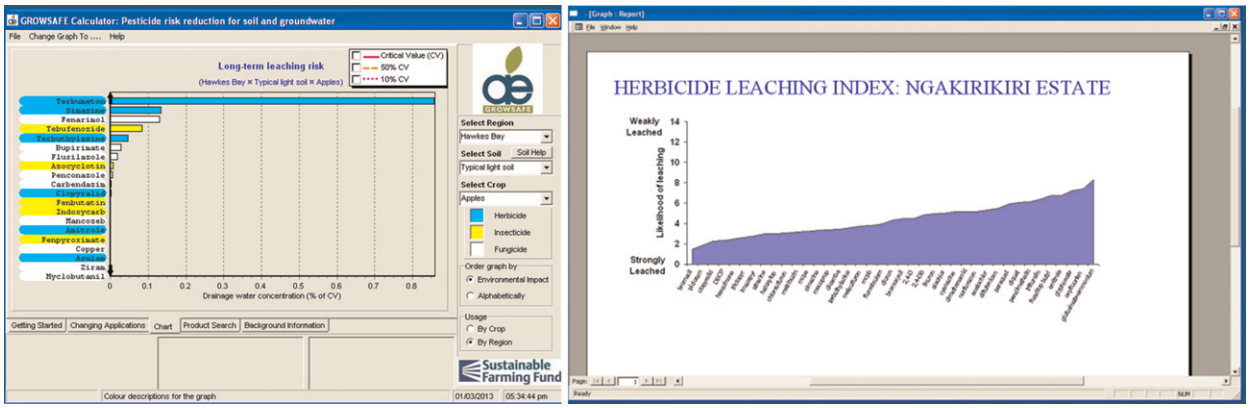

Figure 6 Left: Pesticide risk calculation with the GROWSAFE® Calculator Version 1.0.6.14. Right: Example of the output of the herbicide-leaching likelihood ranking tool PESTPROP. This decision-support tool allows the selection of herbicides with low risk of leaching. PESTPROP uses groundwater ubiquity score (GUS) and the attenuation approach.

et al., 2002), sometimes even at the national or even larger scale (Kruijne *et al.*, 2011).

In principal, pesticide risk assessment tools can be divided into farm-level indicators and complex regional-scale indicators. The latter assist pesticide control advisors and policy makers with the initial screening of pesticides, and regional councils and regulatory authorities to compare different land uses and agricultural management systems with regard to associated environmental pesticide risks (Levitan, 2000; Reus *et al.*, 2002). These indicators consider exposure modeling, which acknowledges the importance of site-specific data on soil characteristics and weather conditions for the fate of pesticides in the environment. Examples are the 1D-deterministic pesticide leaching models SPASMO and PELMO embedded in the pesticide risk indicator GROWSAFE® (Snow *et al.*, 2004) and SYNOPS (Gutsche and Rossberg, 1997), respectively. The Environmental Yardstick for Pesticides uses the PESTLA model to estimate pesticide concentration in groundwater (Reus *et al.*, 2002). Combining pesticide fate models into pesticide risk indicators is desirable. The more comprehensive tools integrate impacts on several environmental compartments and nontarget organisms and take into consideration site-specific data. However, the use of these tools is restricted by the time and effort for gathering the necessary input data, the expertize required to run the models, and the extended calculation time for running the complex models, which in addition requires high-performance computers.

Farm-level indicators assist pesticide users to decide which pesticides to favor in a certain pest control situation. These can be simple scoring tools that focus on the potential contamination of a single environmental compartment by a pesticide. A well-known example is the groundwater ubiquity score (GUS-index), which helps the user to decide which pesticide to select in case the aim is to minimize the potential contamination of aquifers. The assessment is solely based on the persistence and the partitioning coefficient of an active ingredient, that is, the physicochemical properties of the pesticides (Gustafson, 1989). More complex farm-level indicators help pesticide users to better match their pesticide selection with local conditions. Metamodels are elegant solutions that allow pesticide users at the farm level to assess more complex modeling frameworks as described above without the need of expert knowledge, excessive model run-times or data input. An advanced pesticide farm-level risk indicator is a computer-based decision support tool (*p*-EMA) (Brown *et al.*, 2003), which uses the MACRO model to predict pesticide losses to surface and groundwater. MACRO is implemented in *p*-EMA as a metamodel, meaning all the simulations are prerun with the MACRO model and linked to *p*-EMA as a look-up database. FOOT-FS is the successor, a farm-scale tool developed by the FOOTPRINT project (FOOTPRINT, 2010). GROWSAFE® (Snow *et al.*, 2004) is the New Zealand version of a metamodel-based pesticide risk indicator (**Figure 6**). A different promising approach is developing web-based modeling frameworks. For example, the Pesticide Use Risk Evaluation decision support system evaluates site-specific pesticide risks to surface water, groundwater, soil, and air with the ratio between PECs in Californian agricultural systems to the toxicity values of selected endpoint organisms (Zhan and Zhang, 2012).

Apply Agricultural Management Strategies

A range of agricultural management strategies can be employed to minimize the risks associated with pesticide use. Good Agricultural Practice is a key but there are different more specific approaches that are outlined in the next section.

Convert into certified organic agricultural cultivation practices

Converting agricultural production systems into certified organic cultivation conveys the complete ban of all synthetic chemical pesticides. There is an increasing demand for organically grown produce especially in Europe, and the share of land under organic management is rising worldwide. However, the total area of 37.2 million ha of agricultural land under organic management is still small. It represents approximately 1% of the global agricultural land (Willer *et al.*, 2013). Although organic agriculture would immediately eliminate all risks associated with agricultural pesticide usage, it bears other potential problems for growers, society, and the

environment including lower yields and higher demand for agricultural land, more labor-intensive production systems with demand for cheap laborers, food shortages, increased costs of produce, produce not unblemished as desired by the average consumer, lack of research to optimize alternative production strategies, etc. (Gomiero *et al.*, 2011). Environmental benefits are also not always clear. For example, copper preparations and mineral oils are allowed in many countries as fungicides and insecticides in organic agricultural systems, respectively. A recent comprehensive metaanalysis comparing the relative yield performance of organic and conventional agriculture showed that yields from organic agriculture are typically lower than under conventional production systems. In this study, it was also highlighted that under certain conditions organic yields might match conventional yields (Seufert *et al.*, 2012). Seufert *et al.* (2012) concluded that "the factors limiting organic yields need to be more fully understood, alongside assessments of the many social, environmental and economic benefits of organic farming systems."

Apply integrated pest management practices

It is commonly accepted that the use of pesticides will continue to play an important role in modern agricultural production systems. To increase the sustainability of modern agriculture and at the same time ensure high yields and reduce production costs, the use of pesticides has to go hand in hand with IPM practices. The EU is pioneering when it comes to IPM, and have committed to making IPM a reality by requiring European growers to implement the principles of IPM by 2014. Many different descriptions of IPM practices can be found in the literature (Kogan, 1998; Prokopy, 2003). The FAO defined IPM as: "The careful consideration of all available pest control techniques and subsequent integration of appropriate measures that discourage the development of pest populations and keep pesticides and other interventions to levels that are economically justified and reduce or minimize risks to human health and the environment. IPM emphasizes the growth of a healthy crop with the least possible disruption to agro-ecosystems and encourages natural pest control mechanisms." This definition implies that IPM practices should balance economical and environmental and health considerations of pest control. Basic principles of IPM systems include using treatment thresholds to decide when pesticide use is necessary and economically beneficial as opposed to applying pesticides as prophylactic measures. This necessitates that pest and disease levels are monitored accurately in the field. Regional warning systems have been established in many areas. Selecting pesticides with minimum impact on the environment and humans, optimizing application techniques and timing of applications, and applying biological control agents or other alternative pest control strategies (hand weeding and crop rotation) are further basic principles applied in IPM systems (Dent, 2005). The recent EU-project 'Endure' was dedicated to reducing the systematic use of pesticides and promoting IPM. The involved research teams developed an online information center providing information on sustainable crop protection measures tailored to local conditions at country level. Van Eerdt *et al.* (2014) highlighted that quantitative cost–benefit analyses of IPM measures are generally missing, and ascribed this lack to the high regional variability of IPM practices and the difficulty to assess ecological benefits of management changes quantitatively. In addition, their research emphasized the need to understand better the reasons for growers choosing not to adopt IPM measures in order to close the gap between the risk reducing potential of IPM measures and the risk reduction actually achieved by growers in a region. Possible reasons for the lack of adoption may include missing practicability of IPM measures and growers' lack of experience or knowledge to judge potential consequences on yield. Lamine (2011) underscored the role of professional local networks for increasing the rate of growers adopting IPM measures in a region. According to Lamine (2011) such networks provide growers opportunities for exchanging technical experience and learning from each other but also help them to find a different professional identity. The need for extension services and policy advisors to initiate and support respective social dynamics at a local scale was also identified.

Common consequences of implementing IPM practices include the reduction of pesticide volumes used or a change in the use-profile of pesticides. **Figure 7** shows the successful example of introducing IPM measures in New Zealand pipfruit industry. It highlights that both the overall volumes and the potential human, soil, and aquatic ecotoxicity impacts of insecticides used in apple production have substantially decreased (Walker *et al.*, 2009). Between 1995 and 2011, insecticide loading on apples has decreased by 83% with much lower potential (eco)toxicity through implementing sustainability programs. In contrast, van Eerdt *et al.* (2014) found that implementing IPM practices hardly reduced neither the aquatic effects nor the number of pesticide applications. They explained this by the fact that IPM methods usually only target one group of pesticides or a single pest. These authors suggested complementing IPM measures, such as the substitution of high risk pesticides by lower risk pesticides, with other measures including the establishment of wider crop-free buffer strips.

Improve resilience of agricultural production systems

A shift in the focus of agricultural production systems from the sole aim of agricultural production systems to provide food and fiber often culminating in intensive monocultures to agroecological approaches and ecosystem management could improve resilience of agricultural production systems in the future. The development of these concepts is at least partly resulting from the new understanding that our soils, vegetation, biodiversity, aquifers, lakes, streams, and rivers are the natural capital of the Earth and provide ecosystem services to mankind. The Millennium Ecosystem Assessment (MA, 2005) classified ecosystem services into four typologies: the supporting services of soil formation and nutrient cycling, the provisioning service of food, fuel, and fiber production; the regulating services around the buffering and filtering of water, carbon, and gases; and the cultural services of heritage, recreation, and spiritual well-being. Costanza *et al.* (1997) assessed the global flow of ecosystem services from the world's natural capital stocks of materials and energy, and they concluded that the sum value of terrestrial and marine ecosystem services was 1.8 times the value of gross global production. Today, there is a strong pull toward ecosystem management in light of all

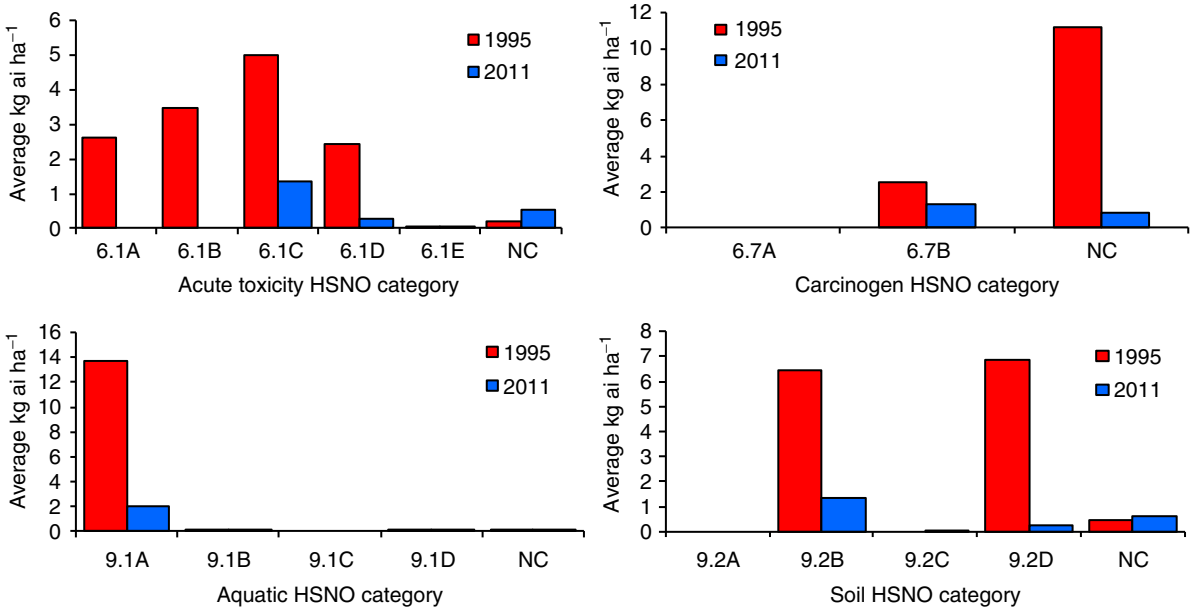

Figure 7 Left: Example of effects of introducing integrated management practices on organophoshate insecticide use on apples in New Zealand (Manktelow *et al.*, 2005). Right: The mean active ingredient use of hazardous substances and new organisms (HSNO) classified 6.1 (human toxicity) and 9.1 (ecotoxic) insecticides applied to apples (Walker *et al.*, 2009).

ecosystem services that the natural capital provides (Winter and Lobley, 2009). In view of this, the European Commission proposes to reward the delivery of environmental public goods, such as permanent grasslands, green cover, crop rotation, and ecological set-aside with the aim to establish refuges and reservoirs for natural antagonists (European Commission, 2010). These measures will result in an increase in the so-called high nature value farmlands, particularly in regions with intensive arable farming (Van Zeijts *et al.*, 2012). High nature value farmlands are characterized by more species diversity. This will – among others – reduce pest attacks and might, therefore, reduce the dependence of chemical pesticides. It will further enhance landscape diversity with the aim to reduce the vulnerability of agricultural production systems and to enhance their resilience (Nicholls and Altierei, 2007).

Enhance Pesticide Life Cycle Stewardship

The conceptual framework of LCS and Extended Product Responsibility could be extended to the stewardship of pesticide products ('Cornell University Information on Research Project'). The framework suggests that all stages of the pesticide life cycle, from product development and manufacture, through distribution and use, to the collection and disposal of unused products and containers should be considered when assessing the risks associated with pesticides. Some practical examples of pesticide stewardship embedded in the European pesticide regulation practices are included in **Table 1**, for example, the postmonitoring of registered pesticides that gives a feedback cycle in pesticide registration. If a given pesticide is frequently detected in groundwater or surface water resources, it will have consequences for the registration of this pesticide in Europe. These consequences include compulsory application of additional risk mitigation measures and withdrawal of the substance from the market. Recently, concepts and tools have been developed that aim at such a holistic environmental assessment of products. These tools include LCAs and product footprinting. The following section is dedicated to explaining the principal ideas of these instruments and provides examples on how these approaches have been applied to the product pesticide.

Conduct life cycle and life cycle impact assessments of pesticides

The first part of this section provides a general introduction to the concept of LCA and the second part describes the current state-of-the-art of applying LCA to pesticides. LCA is a holistic methodology to quantify the potential impacts a good or service has on the environment during its entire life cycle. This definition contains four important terms: life cycle, potential environmental impacts, holistic, and quantification. Life cycle is a fundamental concept in LCA, underlining that a product has a 'cradle' and a 'grave'. A product's use is preceded by design, resource extraction, and production. After use, it is disposed. All these stages may result in environmental impacts that have to be taken into account, as the occurrence of these processes is a direct consequence of the product's existence. The term 'potential environmental impacts' expresses that LCA does not predict the actual environmental effects. Instead the results should be considered as environmental indicators. LCA can be termed holistic to stress the comprehensive scope of the methodology. LCA aims to determine all environmental impacts of all processes related to the life cycle of the studied product, regardless of time or location. Generally, the following impacts are considered: abiotic resource depletion,

greenhouse gas emissions, ozone-depleting emissions, (eco) toxicological impacts, photochemical oxidation, acidification, and eutrophication. These impact categories are far more encompassing than the pesticide effects considered in traditional risk assessments of pesticides. Finally, quantification indicates that LCA is a quantitative methodology, expressing potential environmental impacts in numbers rather than as a qualitative description.

LCA, as defined in the ISO standards 14040 and 14044: 2006, consists of five phases: goal definition, scope definition, inventory analysis (LCI), impact assessment (LCIA), and interpretation. The goal definition describes the motivation for carrying out the study, its purposes, and the target audience. In the scope definition the assessed product is precisely defined. Moreover, a detailed description is given of how the next stages in the LCA will be carried out. In the LCI, all exchanges between the technosphere and the ecosphere, that is, between the product system and the environment, are quantified. For example, in the case of an LCA of a pesticide such exchanges can be emissions of a pesticide to the environment during application, greenhouse gases emitted when producing the pesticide, or the extraction of oil used as a raw material in production. During the LCIA phase the exchanges that were quantified in the LCI are translated into potential environmental impacts. Impact assessment consists of a number of steps that will not be discussed in more detail here. In LCA, the three so-called areas of protection are identified, describing what LCA seeks to protect: natural environment, human health, and resource depletion. Environmental impacts can be modeled at two levels: at endpoint level, which is at the damage inflicted in one of the three areas of protection, or at midpoint level, which means up to any point in the cause-effect chain leading from the environmental exchange to damage. The choice between midpoints and endpoints is one between, among others, uncertainty and ease of communicating results. In the interpretation phase the results from the impact assessment are interpreted. Furthermore, the uncertainty, sensitivity, and consistency of the previous phases are determined. On the basis of this, conclusions are drawn and recommendations are formulated.

There are a number of LCA tools available to assess the environmental impacts of pesticides. Within LCI, inventory analysis, two relevant data sources can be mentioned. The Swiss LCI database Ecoinvent contains inventory data regarding the production of pesticides, on different aggregation levels. This kind of inventory data lists the inputs and outputs to and from the environment required for the production of a given mass of active ingredient. Pesticide-specific data are available for a number of frequently used pesticides and pesticide classes. All data are based on data collected for 78 pesticides used in Europe and the data, therefore, are considered as valid under European circumstances.

Regarding emissions in the use stage of pesticides, when the chemical is applied to the crops, two approaches are currently used in LCA. The first, and dominant, approach is the one applied in crop production processes in the Ecoinvent database. Here, it is assumed that all pesticide used is emitted to the agricultural soil. The second approach is the model PestLCI 2.0 (Birkved and Hauschild, 2006; Dijkman *et al.*, 2012), which calculates emissions from the technosphere to three environmental compartments: air, surface water, and groundwater. An application of the model to leek production is described in de Backer *et al.* (2009). The technosphere in the PestLCI approach is defined as the agricultural field on which the studied crop grows, up to 1 m of depth, as well as the air column above the field, up to 100 m height. Any pesticide leaving this technosphere is considered an emission to the environment. In this approach, the agricultural soil is part of the technosphere. As a consequence there are no pesticide emissions to soil. Emissions to soils outside the technosphere are possible; however, this is considered in LCIA models: in LCI the emissions from the technosphere to the ecosphere are considered, and LCIA models are used to determine the fate of chemicals after they enter the ecosphere. The main reason for excluding the agricultural soil as an emission compartment in PestLCI is that agricultural soil is a highly manipulated soil with reduced biodiversity. Therefore, the soil cannot be considered as a part of the natural environment that LCA seeks to protect.

In the LCIA of pesticides emitted to the environment, a number of tools are available to assess their (eco)toxicity impacts. Most of the recently developed impact assessment methodologies have some way of quantifying these environmental impacts. A frequently applied model is USEtox (Rosenbaum *et al.*, 2008). This model was developed in a consensus process by the developers of a number of toxicity assessment models used in LCA and was found to be the best existing characterization model at midpoint (Hauschild *et al.*, 2013). Besides application in LCIA, USEtox can also be used in comparative risk assessment. USEtox is used to calculate characterization factors for human toxicity and freshwater ecotoxicity impacts of (organic) chemicals. These characterization factors can then be combined with emission data from LCI in order to arrive at the potential environmental impacts. In USEtox, as in other impact assessment models, human toxicity impacts are assessed by means of fate, exposure, and effect factors. These factors, respectively, describe where in the environment a chemical ends up, how much humans are exposed to the chemical, and the damage it does once human beings are exposed. Likewise, freshwater ecotoxicity characterization factors are calculated from fate and exposure factors. Characterization factors are calculated for two geographical scales: continental and global, where the continental scale is nested in the global scale. USEtox users can calculate characterization factors of chemicals not already included in the model by inserting a number of physical and chemical properties of the compound, as well as a limited number of toxicity data.

In current LCA practice, the assessment of environmental impacts is limited to the active ingredient. Although metabolites of the active ingredient sometimes impact the environment, these compounds have so far been ignored in both LCI and LCIA, mainly due to a lack of data.

Promote ecolabeling of food products: Pesticide footprint

As mentioned in the Introduction, increased environmental awareness and changing consumer attitudes are also driving the footprint quantification for products, individuals, activities, businesses, industries, and nations. Of all footprints, the carbon footprint is the most widely used with an internationally

accepted standard, the British PAS2050 (British Standards Institution, 2008). Carbon footprints are measures of the amount of greenhouse gas produced during the life cycle of a product: from its production through processing and storage to its use by the consumer. The labeling of products with carbon footprints allows consumers to choose products according to their global warming potential. The second important incentive for all carbon footprint quantification and analysis is to identify hot spots and to develop mitigation strategies that reduce greenhouse gas emissions. Other footprints are emerging, such as the water footprint, which provide incentives and guidelines for environmentally friendly and economic-sensible production strategies. Ecolabeling is useful for retailers, consumers, and indirectly also for producers (niche products with premium prices). A tool is needed for assessing the environmental impact of pesticides used for producing a specific product. A concept of a pesticide footprint has been proposed that estimates the total loss of pesticides, and the respective impact on humans and ecosystems, per product unit in a life cycle framework. The impact assessment considers how these losses affect humans through the consumption of the product containing residues, and ecosystems through the exposure to residues in the environment (Müller *et al.*, 2010).

Conclusions

Modern agricultural production systems are characterized by innovative management practices and techniques to meet the global food challenge, and the commitment to minimize environmental footprints at the same time and take stewardship of natural capital. There is no doubt that pesticides will continue to play a vital role in these systems. Risks associated with pesticide manufacturing, use, and disposal is inevitable because pesticides are toxic by design. Advances in pesticide risk management are made in partnership of science, industry, government, consumers, and pesticide end-users. Enhanced awareness of consumers, increased product responsibility of pesticide manufacturers and distributors, informed and educated pesticide users, independent expert advisers, and responsible governmental pesticide regulating agencies are enhancing the development of successful pesticide risk reduction strategies. Many different approaches to reduce pesticide impacts on human health and the environment have been developed. In this article, following strategies are introduced: (1) regulate and control pesticide production and use, (2) promote safe pesticide use, (3) apply pesticide risk assessment tools to optimize pest management, (4) apply agricultural management strategies, and (5) enhance pesticide LCS. Regulation of pesticide production and use is indispensable for reducing pesticide risks. It has led to minimizing or banning the use of pesticides in critical areas for environmental and health reasons in the past. Similarly, training, information, and raising awareness to enhance safe pesticide use are necessary but these strategies would not automatically translate into reducing risks. The biggest problem for these strategies to be successful is to establish effective communication channels and to present information in a form accessible to end-users. The development of risk assessment tools goes hand in hand with research. The current knowledge and understanding of pesticide risks is based on experimental research and the modeling of pesticide fate and effects. The application of risk assessment tools is an important part of successful pesticide registration and regulation. To what extent farm-level risk assessment indicators are actually applied on farms and contribute to the reduction of pesticide risks is questionable. Applying agricultural management strategies to reduce pesticide risks has not been widely adopted. The percentage of organic agricultural land has not yet reached 1% of the total agricultural land worldwide. Reasons for the lack of adoption of IPM measures may include missing practicability of IPM measures, growers' lack of experience, and knowledge to judge potential consequences on yield, as well as a general lack of quantitative cost–benefit analyses of IPM measures. Economic constraints may force farmers to concentrate on productivity rather than environmental and ecosystem aspects of their management decisions. Governments and industry foster the idea of pesticide LCS, a concept, which might lead to more tangible benefits in the future if it was embedded in the regulations of pesticide registration.

Glossary

Agrobacterium A soil bacterium that infects susceptible plants and genetically transforms the infected plant. Certain species of *Agrobacterium* (e.g., *A. tumifaciens*) is used in the laboratories to genetically transform desired plants for crop improvement.

Coat protein (CP) A viral structural protein that is the only or the major component of the proteinaecious coat of the virus that encapsulates the viral genetic material.

Genetic transformation Transformation of an organism (plant, animal, or a microorganism) for a desired phenotype (trait) using a manipulated DNA fragment (transgene) from another organism (plant, animal, or a microorganism).

Hermaphrodite/hermaphroditic A hermaphrodite is a bisexual organism (plant, animal, or a microorganism) with both male and female characteristics.

Micropropagation Propagation of plants by artificial means from tissues developed from a single plant cell or a tiny piece of plant tissue.

Particle bombardment/biolistics Particle bombardment, or biolistics, is a commonly used method for genetic transformation of plants or other organisms. Transgene DNA-coated metal (gold or tungsten) particles are shot at target cells or tissues using a biolistic device or gene gun. The DNA elutes off the particles that lodge inside the cells, and may be stably incorporated in the chromosomes of target cells or tissues.

PTGS Posttranscriptional gene silencing (PTGS) is the silencing of a gene after its transcription by cleaving or inactivating the transcribed messenger RNA.

RNA silencing Silencing of a gene after its transcription by cleaving or inactivating the transcribed messenger RNA. RNA silencing is also called posttranscriptional gene silencing (PTGS).

Transgene A manipulated DNA fragment from an external source (plant, animal, or a microorganism) used to genetically transform a desired organism (plant, animal, or a microorganism) for a desired phenotype (trait).

Transgenic plant A plant genetically transformed for a desired phenotype (trait).

Papaya Is the Fruit of Angels

Papaya (*Carica papaya* L.) is a short-lived and fast-growing perennial herbaceous plant with a single stem and a crown of large, palmately lobed leaves, producing fleshy delicious fruits, from 8 to 10 months after transplantation in the field. The famous explorer and colonist Christopher Columbus called papaya the "Fruit of Angels." In the seventeenth century, Chinese tribes recognized papaya as a source of traditional medicine and used it for curing certain diseases, including malaria and gastrointestinal infections. Papaya is believed to be indigenous to the tropical regions of Central America. Introduced in Caribbean countries and Southeast Asia during the Spanish exploration in the sixteenth century (Storey, 1969), papaya crop spreads rapidly to the Indian subcontinent and Africa and is distributed widely today throughout tropical and subtropical regions of the world.

Papaya is an important cash crop in the tropics and subtropics and it is economically important because of its edible fruits rich in vitamins A and C (Manshardt, 1992) and latex rich in papain and chymotrypsin with applications in the beverage, food, cosmetic, and pharmaceutical industries (Chan and Tang, 1978). India, Brazil, Indonesia, Nigeria, and Mexico account for more than 70% of the global papaya production (**Table 1**). With a global productivity of 6.85 million metric tons, papaya is one among the 10 most important fruit crops of the world, the others being apple, avocado, banana, grape, mango, pear, pineapple, strawberry, and tomato. However, the relatively fragile and perishable nature of papaya fruit causes it to lag behind several of these major fruits in production, value, and export. Of the global annual quantum of papaya fruit production, only a small fraction of nearly 2% is being exported (Bapat *et al.*, 2010).

Worldwide Threat on Papaya Production by *Papaya Ringspot Virus*

Papaya cultivation is affected by a number of diseases caused by various pathogens. Papaya productivity is limited in many areas of the world due to the ringspot disease caused by the aphid-borne *Papaya ringspot virus* (PRSV), the major obstacle to large-scale commercial production of papaya (Purcifull *et al.*, 1984; Yeh and Gonsalves, 1984). PRSV was first reported in Hawaii in the 1940s (Jensen, 1949a), and subsequently, its prevalence in Florida (Conover, 1964), Caribbean countries (Adsuar, 1946; Jensen, 1949b), South America (Herold and Weibel, 1962), Africa (Lana, 1980), India (Capoor and Varma, 1948; Singh, 1969), the Far East (Wang *et al.*, 1978), and Australia (Thomas and Dodman, 1993) was noticed.

In papaya, PRSV causes symptoms of severe mosaic and distortion of leaves, ringspots on fruits, and water-soaked oily streaks on the upper stems and petioles. It severely affects the growth and development of papaya plants and drastically

Table 1 World papaya production in 2011

Country	Hectare	Metric ton
	(×1000)	(×1000)
India	104.3	4 180.1
Brazil	35.5	1 854.3
Indonesia	11.1	958.3
Nigeria	94.0	705.0
Mexico	14.2	634.4
Ethiopia	17.9	340.2
D. R. Congo	13.2	280.3
Thailand	13.2	271.9
Guatemala	2.2	205.5
China	7.3	181.2
Philippines	8.6	157.9
Colombia	5.0	153.2
Cuba	5.8	135.0
Peru	9.2	125.8
Venezuela	6.6	125.6
Others	73.4	1 503.0
Total	421.5	11 838.7

Source: Data digested from Food and Agriculture Organization (FAO), Statistical Division, 2013 (Available at: http://faostat.fao.org/faostat/).

reduces the number, size, and quality of the fruits and thus causes severe economic loss to growers (**Figure 1(a–c)**). In nature, PRSV is transmitted nonpersistently by aphids (**Figure 1(d)**) (Purcifull *et al.*, 1984) and is mechanically sap-transmissible. Apart from the predominant mosaic strains of PRSV, certain strains of PRSV cause severe wilting and death of the infected plants (Chang, 1979). To date, most of the papaya plantation areas of the world suffer devastation by this virus and lack of an effective control measure completely thwarts the farmers from opting for papaya cultivation. PRSV was reported in 1975 from the southern part of Taiwan, and it destroyed most of the papaya plantations in the country within a few years and caused unprecedented yield loss (Wang *et al.*, 1978).

The aphid-borne PRSV belongs to the genus *Potyvirus* of the family *Potyviridae* (King *et al.*, 2011), one of the largest and economically important plant virus groups. The virion of PRSV is a 780×12 nm flexuous particle (**Figure 1(e)**) with a positive sense single-stranded RNA genome (De La Rosa and Lastra, 1983; Yeh and Gonsalves, 1985). The genomic RNAs of several PRSV strains, including those from Hawaii (Yeh *et al.*, 1992) and Taiwan (Wang and Yeh, 1997), have been sequenced. The PRSV genomic RNA is 10.3 kb in length and it encodes a single polyprotein that is proteolytically processed by three virus-coded proteases into nine final proteins, including the 36 kDa coat protein (CP) for encapsidation of the viral genome (Purcifull and Hiebert, 1979; Gonsalves and Ishii, 1980; Yeh *et al.*, 1992) and the proteins of cylindrical (Purcifull and Edwardson, 1967) and amorphous (Martelli and Russo, 1976) inclusions in the cytoplasm of the infected host cells. The PRSV genomic RNA is uncapped, but it possesses a covalently attached molecule of VPg protein at the 5′ end and a polyA tail at the 3′ end. The first reported PRSV genome contains 10 326 nucleotides with a genetic organization of 5′-leader, P1, HC-Pro, P3, CI, 6K, NIa (processed further into VPg and NIa protease), NIb, CP, and 3′-noncoding region (Yeh *et al.*, 1992). The genetic organization and gene functions of PRSV are presented in **Figure 1(f)**.

No Natural Source for Resistance Breeding and No Effective Control Measures by Agricultural Practices

The species of *C. papaya* lacks effective natural resistance to PRSV and hence conventional breeding of papaya for PRSV resistance is impractical (Cook and Zettler, 1970; Wang *et al.*, 1978). However, PRSV-tolerant lines of papaya have been reported (Cook and Zettler, 1970; Conover, 1976; Conover *et al.*, 1986). Though PRSV-tolerance trait was introduced into several papaya cultivars, the horticultural properties, such as shorter shelf life on markets and more susceptibility to *Phytophothora* fruit- and root-rots, of the resultant papaya lines were not commercially desirable (Mekako and Nakasone, 1975; Conover and Litz, 1978; Yeh and Gonsalves, 1994).

A dominant gene conferring resistance to PRSV P is known to exist in certain wild relatives of papaya such as *C. cauliflora*, *C. stipulata*, and *C. pubescens* (Horovitz and Jimenez, 1967). Certain interspecific reproductive barriers restrict the transfer of the resistance gene of these *Carica* species into *C. papaya* genome (Horovitz and Jimenez, 1967; Manshardt and Wenslaff, 1989). However, fertile interspecific hybrids and F_2 population were obtained from the cross between *C. papaya* and *C. cauliflora* through embryo rescue technique (Khuspe *et al.*, 1980). The success of interspecific hybridization between *C. papaya* and *C. cauliflora* depends on the parental genotypes (Manshardt and Wenslaff, 1989; Azad *et al.*, 2012). To date, no report is available for success in incorporating the resistance from the wild papaya species to the edible papaya.

Other control measures against PRSV, including agricultural practices such as protecting young seedlings with plastic bag after transplanting, spraying pesticides or mineral oil against PRSV-transmitting aphids, eradicating diseased plants in orchards, mulching soil with reflective silver-colored plastic sheet, intercropping of papaya plants with corn as a high-stem barrier, provide only transient and inadequate protection from PRSV infection (Wang *et al.*, 1987; Yeh and Gonsalves, 1994).

Control of *Papaya Ringspot Virus* by Cross-Protection

An earlier infection of a plant by a virus can induce the plant to develop resistance against subsequent infection by the same virus species and closely related species (McKinney, 1929). Hence, mild virus strains that produce attenuated symptoms on crops without adverse effects can be employed to cross-protect crop plants against severe strains of the virus, which otherwise cause high yield loss. In the late 1980s, to find an effective solution to the severe yield loss caused by PRSV, Gonsalves and coworkers at Cornell University and the University of Hawaii initiated attempts involving cross-protection of papaya using a nitrous acid-induced mild strain of PRSV to protect papaya plants from severe infection of PRSV (**Figure 2(a)**).

In this strategy, healthy crop plants of economically important crops are infected with an attenuated strain of a virus to protect the crop against economic damage by severe strains

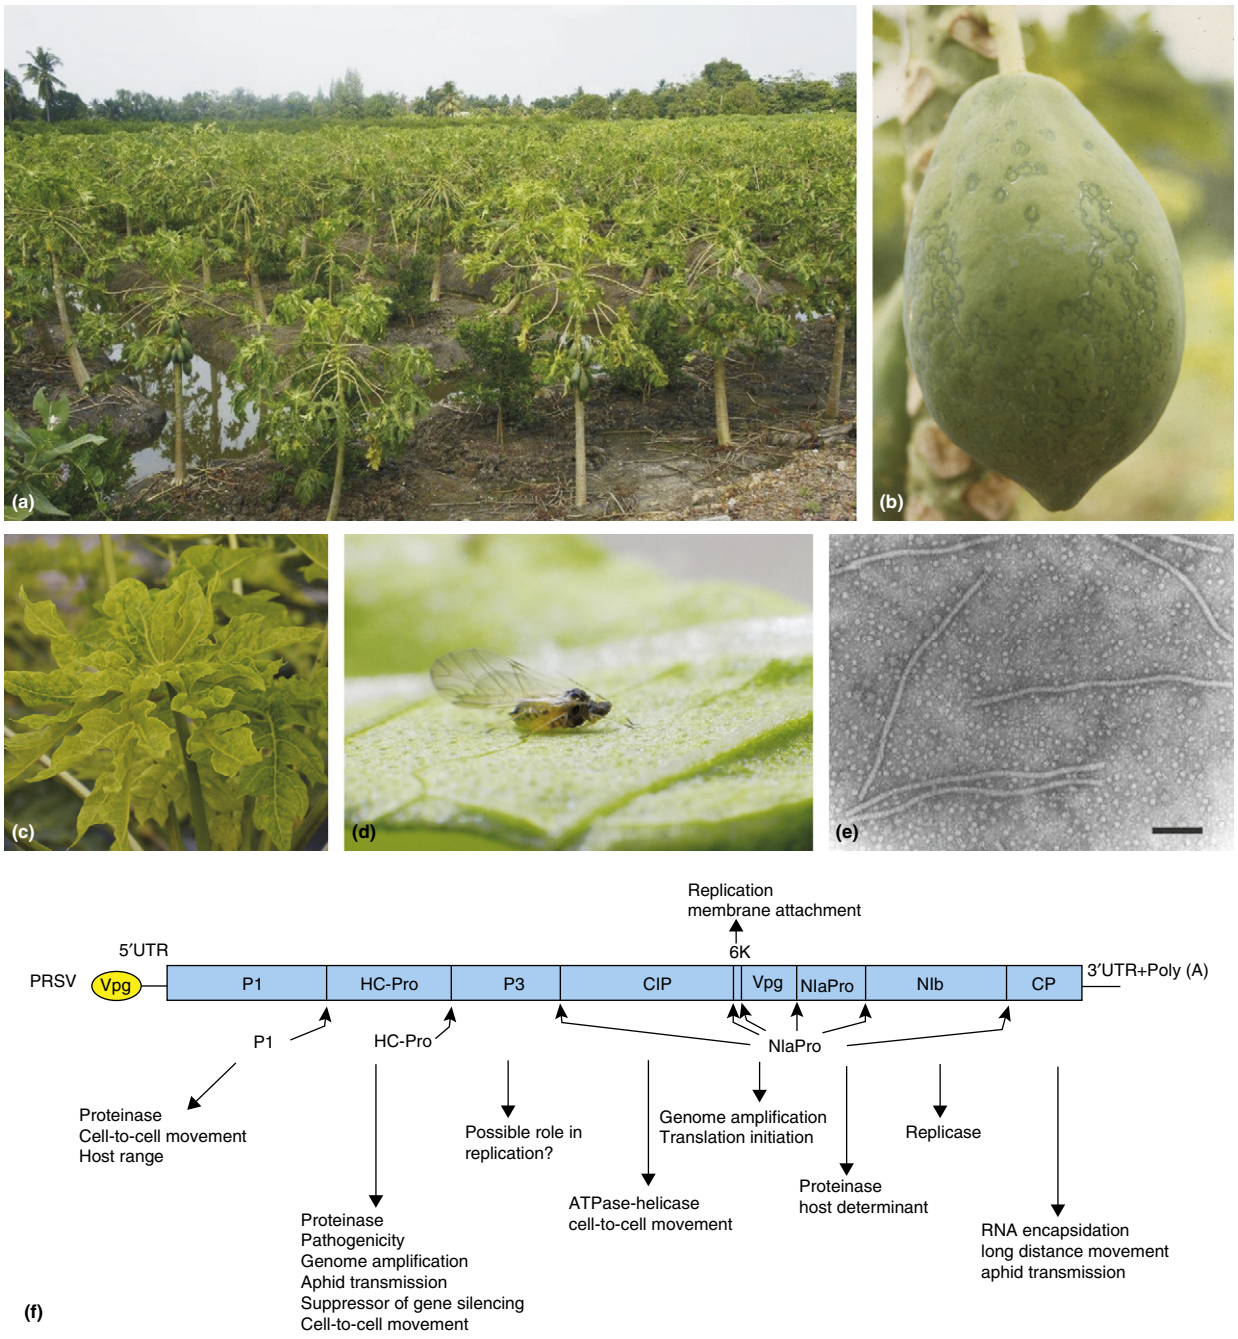

Figure 1 Disease symptoms, aphid vector and particles of *Papaya ringspot virus* (PRSV). (a) A papaya plantation devastated by PRSV. (b) and (c) Symptoms of ringspots on papaya fruit, and mosaic on papaya leaves, respectively. (d) Alate (winged) aphid, the insect vector transmitting PRSV, perching on a papaya leaf. (e) PRSV particles under electron microscope; the scale bar represents 100 nm. (f) Genetic organization and gene functions of PRSV.

of the same virus (Gonsalves and Garnsey, 1989). An attenuated mutant strain of PRSV, designated HA 5-1, was selected following nitrous acid mutagenesis of a severe strain HA originating from Hawaii (Yeh and Gonsalves, 1984). PRSV HA 5-1 was tested extensively in the field and has been used widely in Taiwan and Hawaii since 1985 to permit an economic return from papaya production (Wang *et al.*, 1987; Yeh *et al.*, 1988; Yeh and Gonsalves, 1994). Similar genetically stable, broad-spectrum attenuated strains of major papaya-infecting viruses may be screened from natural sources or engineered in the laboratory for effective cross-protection.

The effectiveness of cross-protection strategy is limited by several technical and practical difficulties, including non-availability of efficient and genetically stable attenuated strains, superinfection by virulent strains, requirement for a large-scale inoculation facility, and insufficient protection

Figure 2 Effective control measures of *Papaya ringspot virus* (PRSV) by cross-protection and netting. (a) Papaya seedlings were mass-inoculated with a mild strain PRSV HA 5-1 by pressure spray (1) and kept in insect-proof nethouse (2). The HA 5-1 cross-protected papaya plant was resistant to severe infection of PRSV HA (3); cross-protected papaya plants loaded with fruits in Taiwan (4); HA 5-1 protected plants loaded with fruits versus unprotected fruitless plants with severe symptoms in a Hawaii field test (5). (b) A papaya orchard protected by netting to avoid PRSV infection (1); Destruction of the protective net by a tropical storm (2). Reproduced with permission from Yeh, S.D., Gonsalves, D., Wang, H.L., Namba, R., Chiu, R.J., 1988. Control of *Papaya ringspot virus* by cross protection. Plant Disease 72, 375–380.

against different strains in different regions (Stubbs, 1964; Gonsalves and Garnsey, 1989; Yeh and Gonsalves, 1994). To reduce the loss from infection by severe strains of viruses, cross-protection strategy may be used along with other control measures, according to the nature of crops and specific situations of geographical regions. However, the success of cross-protection strategy is greatly dependent on efficient large-scale inoculation and complete farmer cooperation during every round of cultivation. In Taiwan, this method was used for control of PRSV during 1984–93, with 200–250 hectors annually applied (Yeh and Gonsalves, 1994). In Hawaii, the cross-protection is working fine against local strains, but the method is not widely extended because of the new control strategy by genetically engineered transgenic resistance. In Thailand, the cross-protection was introduced, but was not widely accepted because HA 5-1 did not provide good protection against Thai PRSV strains (Yeh and Gonsalves, 1994).

Effective Control of *Papaya Ringspot Virus* by Netting

Protecting transplanted seedlings with fine UV-resistant nylon net (32 mesh) by covering the entire orchards provides complete exclusion of aphids that transmit PRSV, and thus guarantees papaya yield (Wang *et al.*, 1987; Yeh and Gonsalves, 1994). After 1994, this method has become the major PRSV control measure in Taiwan, replacing original cross-protection strategy. Currently, a total of 3207 ha papaya orchards are under netting in Taiwan, representing the largest netting cultivation of a perennial fruit crop in the world (**Figure 2(b)**).

The 47 ton ha^{-1} average production of papaya under netting is also the highest production per unit area in the world (COA Agricultural Statistics Yearbook, 2011). However, although such a high production is guaranteed, the flavor and sweetness of the fruits are inferior because the intensity of the sunshine is significantly cut off by the netting. Though this method increases papaya productivity significantly, the accumulating synthetic nylon materials that are difficult to dispose and the hazardous materials produced during burning of those nondegradable polymers are a serious concern, and thus not approved by ecologically conscious people. Also, the high cost for the construction of the netting system, approximately 25 000 US dollars per hectare, is a serious hurdle for small-scale papaya growers. When a tropical storm typhoon hits the island (average 3.5 times a year), most of the papaya growers lose not only the crop, but also the whole netting system. Thus, this is a high cost and risky cultivation method.

Control of *Papaya Ringspot Virus* by RNA Silencing-Based Transgenic Resistance

A disease-susceptible plant can be genetically transformed into disease-resistant plant by incorporation of an appropriate portion of a pathogen's genome into the plant (host) genome. This application is based on the phenomenon of pathogen-derived disease resistance (PDR) (Sanford and Johnston, 1985). For PDR, segments of a pathogen genome can be excised and modified in the laboratory into transgenes and delivered into a plant host by means of particle bombardment (biolistics) or *Agrobacterium*-mediated gene delivery (Chiton, 1983). The genetically transformed plant expresses a pathogen component (a RNA or protein) from the transgene, which sensitizes the plant against the invading pathogen or blocks a crucial phase of pathogen life cycle and thus averts the disease.

Originally, the effectiveness of PDR was critically validated by Beachy and coworkers (Powell-Abel *et al.*, 1986) in the case of the resistance to *Tobacco mosaic virus* (TMV) conferred by the transgenic tobacco lines carrying the CP gene of TMV. The CP gene-mediated transgenic resistance has been proven effective in protecting tobacco, tomato, potato, and other crops from infection by many different RNA viruses (Beachy, 1990; Lomonossoff, 1995; Goldbach *et al.*, 2003). The health and environmental issues can be alleviated or totally avoided by selecting appropriate sequences from pathogens and engineering them into safer transgenes to preempt the possibility of their expression and/or persistent presence of pathogenic proteins or RNA sequences in transgenic hosts. RNA silencing-mediated transgenic resistance is one of the strategies that does not create pathogenic nucleotide sequences or proteins in the host, and hence is totally human-, livestock-, and environment-friendly. In host cells, the long double-stranded RNAs and hairpin-structured RNAs produced by the virus-derived transgene is processed by the host Dicer-like (DCL) protein into a class of small RNAs designated as small interfering RNAs (siRNA). These siRNAs are loaded into RNA-induced silencing complexes (RISCs) containing an ARGONAUTE protein. The siRNAs, which are complementary to the RNA (genome) of the invading virus, is used by the host posttranscriptional gene silencing (PTGS) machinery as a guide RNA to locate the viral genomic RNAs to destroy them (Khvorova *et al.*, 2003; Zamore and Haley, 2005). Excellent reviews (Frizzi and Huang, 2010; Wang *et al.*, 2012) describing the process of PTGS have been published.

The elimination of viral transgenic RNA and viral genomic RNA and prevention of translation of transgenic and viral proteins in the PTGS (RNA silencing)-mediated transgenic plants encouraged many groups to adopt this strategy. Pathogen-derived resistance has been engineered in many economically important crops, and the effective virus resistance of the resultant transgenic lines has been demonstrated (Yeh *et al.*, 2010).

Coat Protein-Transgenic Papaya Resistant to *Papaya Ringspot Virus* Saves Papaya Industry in Hawaii

Papaya is the second largest fruit crop in Hawaii. It is grown commercially for export to the US mainland and Japan. Hawaii exports 25–30% of its produced papaya to Japan. However, the successful present-day Hawaiian papaya industry has a troubled past due to PRSV. In early 1950s, PRSV devastated papaya production on Oahu, forcing the papaya industry to relocate to the Puna district on the Big (Hawaii) Island from the early 1960s. Despite Puna's proximity to the almost abandoned PRSV-infested area, the geographical isolation of Puna and the efforts of the farmers by diligent eradication of diseased plants under the guidance of scientists kept PRSV away from Puna for years. Puna farmers produce 95% of Hawaii's papaya.

First Successful Case of Genetically Modified Fruit Crop for Commercialization

However, the impending danger of PRSV reaching Puna necessitated permanent solution to the PRSV problem. In the late 1980s, to find an effective solution to the severe yield loss caused by PRSV, Gonsalves and coworkers at Cornell University and the University of Hawaii initiated attempts to generate PRSV CP transgenic papaya lines resistant to PRSV. The CP gene of PRSV HA 5-1 was constructed and delivered into payaya genome via particle bombardment (biolistics) of embryogenic tissue derived from premature zygotic embryos of papaya. Tansgenic papaya lines were obtained after regeneration of transformed cells through selection and regeneration steps (Fitch and Manshardt, 1990; Fitch *et al.*, 1992). Under greenhouse and field conditions, the individuals of the PRSV CP transgenic line (55-1) of SunUp papaya cultivar were highly resistant to infection by PRSV isolates originating from Hawaii (Fitch *et al.*, 1992; Lius *et al.*, 1997).

The field trials of the CP transgenic homozygous line of SunUp and CP transgenic hemizygous line of Rainbow indicated their efficacy in managing PRSV in Hawaii (Ferreria *et al.*, 2002). The PRSV resistance of SunUp cultivar is triggered mostly by RNA silencing (Gonsalves, 2002), a process of specific degradation of mRNA responsible for transgenic resistance to plant pathogens (Baulcombe, 1996; Baulcombe, 1999; Hamilton and Baulcombe, 1999). The strong operation of PTGS is likely to be the basis of the estimated 87–99%

reduction in CP levels in the plants of 55-1 line-derived Rainbow and SunUp (Fermín *et al.*, 2011), in comparison to PRSV-infected wild type papaya. Based on the biosafety and economic benefits, these CP transgenic lines of Rainbow and SunUp cultivars of papaya were deregulated in May 1998 by the US Animal and Plant Health Inspection Service and Environmental Protection Agency, and granted approval from the Food and Drug Administration for commercial application (Gonsalves, 2002). This is the first successful case of a transgenic fruit tree being commercialized in the world. Later, PRSV CP transgenic papaya was deregulated in Canada (Suzuki *et al.*, 2007) and Japan (Gottula and Fuchs, 2009).

The Genetically Modified Papaya Cannot Be Applied Outside Hawaii

Owing to the geographical isolation and homogenous PRSV strains in Hawaii, no resistance breakdown has been recorded to date (2013). The Hawaiian papaya industry relies on the PRSV CP transgenic papaya to maintain the production and export of the fruit to US continent, Canada, and Japan. However, the sequence homology-dependent resistance through PTGS on viral CP genes limits the application of these two transgenic cultivars for the management of other PRSV strains in regions out of the geographically secluded Hawaii (Tennant *et al.*, 2001; Gonsalves, 2002). In the case of papaya, a CP transgenic hemizygous line of the cultivar Rainbow, a hybrid derived by crossing a CP transgenic homozygous line of SunUp with nontransgenic cultivar Kapoho, is susceptible to PRSV isolates exotic to Hawaii. However, the CP transgenic homozygous line of the cultivar SunUp is resistant to a wider range of isolates from Jamaica and Brazil, though it is susceptible to isolates from Thailand and Taiwan (Gonsalves, 1998; Tennant *et al.*, 2001; Gonsalves, 2002). The characteristic of sequence homology-dependence of transgenic resistance limits the application of CP transgenic papaya for controlling PRSV in geographical regions other than Hawaii.

Coat Protein-Transgenic Papaya Facing Complicated Situations in Taiwan

In Taiwan, the first PRSV CP transgenic papaya lines resistant or immune to PRSV were generated as early as 1996 (Cheng *et al.*, 1996). Subsequently, PRSV-PLDMV (*Papaya leaf-distortion mosaic virus*) chimeric CP transgenic papaya lines (Kung *et al.*, 2009; for details, see Section Generation of Double Resistance Against *Papaya Ringspot Virus* and *Papaya Leaf-Distortion Mosaic Virus*), PRSV HC-Pro transgenic papaya lines (for details, see Section Threats by *Papaya Ringspot Virus* Super Strains Selected by Coat Protein-Transgenic Resistance and the Solution), and hybrid transgenic papaya lines pyramided with these transgenes (unpublished) have been generated for more effective virus resistance. Though the useful PRSV- and PLDMV-resistant transgenic papaya lines generated in Taiwan have not been deregulated, they have been subjected to long and intensive field evaluations during the period 1996- to date. In parallel, effective genetic transformation and micropropagation methods, which materialize the generation of farmer-preferred all-hermaphrodite population of papaya plants that yield fruits of higher market value, have been developed; the optimized transformation and micropropagation procedures also shorten posttransformational breeding time (also see Sections Current Advances on Papaya Biotechnology, Environmental and Food Safety Assessments of Transgenic Papaya and International Trading, and Concluding Remarks). Overall, the long-term studies from field and laboratory provide useful insights and improve the effectiveness of GM papaya with single-virus, double-virus, or super-virus transgenic resistance. The details are provided in subsequent sections.

The Development of Coat Protein-Transgenic Papaya with Broad-Spectrum Resistance to Different Geographical *Papaya Ringspot Virus* Stains

In Taiwan, the CP gene of a native PRSV strain, designated YK, was used to generate PRSV-resistant transgenic lines of the elite hybrid papaya cultivar Tainung No. 2 by *Agrobacterium*-mediated trasnsformation (Cheng *et al.*, 1996). The transgenic lines showed various levels of resistance, ranging from a few days of delay in PRSV symptom development to complete immunity to the virus (Bau *et al.*, 2003). Several PRSV YK CP transgenic lines, which were highly resistant to the homologous indigenous strain (PRSV YK), also provided wide-spectrum resistance to exotic strains from three different geographical regions, Hawaii, Thailand, and Mexico (Bau *et al.*, 2003) (**Figure 3(a)**). During several field trials from 1996 to 1999, these PRSV YK CP transgenic papaya lines exhibited high degrees of consistent protection against PRSV in Taiwan (Bau *et al.*, 2004).

However, 18 months after plantation in the fourth field trial, unexpected symptoms of severe distortion of fully expanded leaves, stunting of shoot apex, water-soaking on petioles and stem, and yellow ringspots on fruits were noticed on the plants of these lines. The causal agent was distinguished from PRSV by its distinct host reactions and serological properties, and identified as a P type strain PLDMV (Bau *et al.*, 2008), a potyvirus reported from Okinawa, Japan, in 1954 (Maoka *et al.*, 1996). The identified P type Taiwan strain of PLDMV, designated P-TW-WF, was found to be distinct from those from Japan by its inability to infect several cucurbit hosts (Bau *et al.*, 2008), which were reported to be infected by the Japanese strains (Maoka *et al.*, 1996; Maoka and Hataya, 2005). Because all of PRSV CP transgenic papaya lines were susceptible to PLDMV P-TW-WF infection, PLDMV was considered as an emerging threat for the application of the transgenic papaya in Taiwan and other regions (Bau *et al.*, 2008). This situation revealed the urgent necessity for controlling the newly emerging potyvirus PLDMV along with the predominant PRSV in Taiwan and elsewhere (Bau *et al.*, 2008).

Generation of Double Resistance Against *Papaya Ringspot Virus* and *Papaya Leaf-Distortion Mosaic Virus*

Transgenic crops with resistance to multiple viruses can be generated by engineering the plants with CP genes from more than one virus. For generating transgenic papaya lines with resistance to both PRSV and PLDMV, an untranslatable

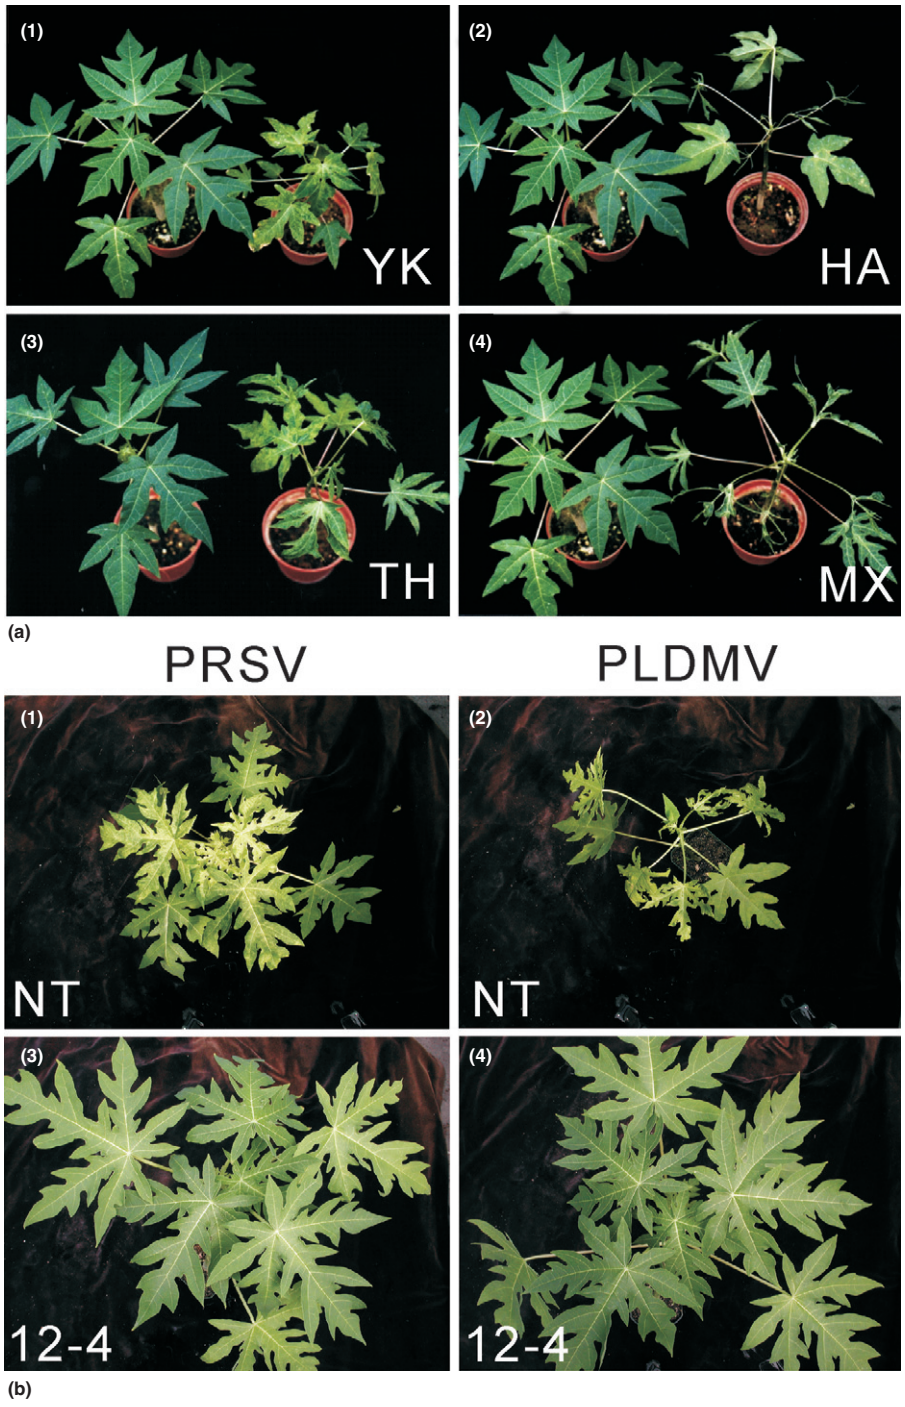

Figure 3 Broad-spectrum resistance of coat protein (CP)-transgenic papaya lines showing single-virus (a) and double-virus resistance (b) to different papaya viral strains. (a) *Papaya ringspot virus* (PRSV) CP transgenic papaya line 19-0-1 showing broad-spectrum resistance to PRSV strain of Taiwan YK (1), Hawaii HA (2), Thailand TH (3), and Mexican MX (e) in contrast to the severely infected nontransgenic papaya plants (1,2,3, and 4 plants at the right). Reproduced with permission from Bau, H.J., Cheng, Y.H., Yu, T.A., Yang, J.S., Yeh, S.D., 2003. Broad spectrum resistance to different geographic strains of *Papaya ringspot virus* in coat protein gene transgenic papaya. Phytopathology 93, 112–120. (b) Double resistance to PRSV and *Papaya leaf-distortion mosaic virus* (PLDMV) conferred by transgenic line 12-4 carrying a PRSV-PLDMV chimeric CP transgene. Nontransgenic papaya plants were susceptible to PRSV (1) and PLDMV (2), whereas the plants of line 12-4 were resistant to PRSV (3) and PLDMV (4). Reproduced with permission from Kung, Y.J., Bau, H.J., Wu, Y.L., *et al.,* 2009. Generation of transgenic papaya with double resistance to *Papaya ringspot virus* and *Papaya leaf-distortion mosaic virus*. Phytopathology 99, 1312–1320.

chimeric construct comprising untranslatable segments of PRSV YK CP and PLDMV P-TW-WF CP genes was constructed and transferred into papaya cv 'Thailand' by *Agrobacterium*-mediated transformation (Kung *et al.*, 2009). The transgenic papaya lines carrying the chimeric CP gene construct were regenerated and micropropagated. Several of the generated PRSV-PLDMV CP transgenic papaya lines exhibited resistance against both PRSV and PLDMV under greenhouse conditions. Molecular analysis of these plants revealed that the transgenic resistance of these plants to PRSV and PLDMV is triggered by the PTGS mechanism. Three lines (10–4, 14–1 and 14–3) showed high degrees of resistance not only to PLDMV P-TW-WF and PRSV YK, which were the transgene donors, but also to the heterologous strains of PRSV MX, TH, and HA, originated respectively from Mexico, Thailand, and Hawaii (Kung *et al.*, 2009) (**Figure 3(b)**). These transgenic papaya plants with PRSV and PLDMV resistance are considered to have a great potential for the control of PRSV and PLDMV in Taiwan and elsewhere (Kung *et al.*, 2009).

Threats by *Papaya Ringspot Virus* Super Strains Selected by Coat Protein-Transgenic Resistance and the Solution

In Taiwan, apart from the PLDMV infection of PRSV CP transgenic papaya lines, they also encountered certain extremely virulent PRSV super strains, including PRSV 5–19. These super strains were able to infect not only the PRSV-resistant transgenic papaya lines (Tripathi *et al.*, 2004), but also the PRSV-PLDMV resistant transgenic papaya lines (You, 2005; Kung *et al.*, 2009). Ironically, the super strain 5–19 was able to breakdown the resistance of the transgenic lines carrying PRSV strain YK CP gene, which shares over 95% nucleotide identity with the CP of 5–19. This level of sequence identity is lesser than those of other PRSV strains that are not virulent enough to overcome the transgenic resistance conferred by YK CP transgene (Tripathi *et al.*, 2004), indicating that the breakdown of the transgenic resistance by 5–19 is not correlated to the sequence divergence between the infecting virus and the transgene.

Subsequent detailed studies on PRSV 5–19, YK, and their recombinants revealed that PRSV 5–19 possesses a stronger gene-silencing suppressor HC-Pro, which can suppress the RNA silencing-mediated transgenic resistance in a transgene sequence homology-independent manner (You, 2005; other unpublished data). Hence, PRSV super strains like 5–19 are regarded as potential threats to the CP gene-mediated single-virus or double-virus resistance of transgenic papaya lines. Such breakdown of transgenic resistance by a strong gene-silencing suppressor of a super strain has strong impacts on the application of transgenic crops for virus control. Moreover, as suggested by the case of PRSV 5–19, the super stains can also wipe out the nontransgenic papaya orchards and cause extreme economic damage.

To disarm the defensive ability of the invading PRSV super strains, new transgenic lines of the papaya cultivar Sunrise carrying the untranslatable full, *N*-, and *C*- terminal region of HC-Pro coding sequences were developed by *Agrobacterium*-mediated transformation of somatic embryos derived from selected hermaphrodite individuals of elite varieties. Several HC-Pro transgenic lines show high levels of resistance to both super strain PRSV 5–19 and other severe strains from Taiwan, Hawaii, Thailand, and Mexico (unpublished data). In the highly resistant lines, low levels of accumulation of mRNA and higher levels of accumulation of siRNA of transgene were observed, suggesting that PTGS was the underlying mechanism for resistance. Such approach is considered more effective than the CP approach, in which HC-Pro can still be processed by autocleavage from the *N*-terminal part of the translated polyprotein to suppress PTGS targeting CP coding sequence that is far down-stream and close to the 3′ terminus of the genome. The results indicated that papaya lines carrying an untranslatable silencing suppressor gene HC-Pro of a PRSV virulent strain can solve the problem resulting from PRSV super strains that create homology-independent transgenic resistance breakdown (unpublished data).

Papaya Production Is Seriously Limited by *Papaya Ringspot Virus* in Southeast Asian Countries

Papaya ringspot disease is the major constraint to papaya production and it causes serious economic loss in Southeast Asian countries, including India, Indonesia, Malaysia, Philippines, Singapore, Thailand, and Vietnam (CABI, 2012; http://www.cabi.org/isc/). The gravity of the PRSV-caused devastation of papaya production and economic loss in these countries can be understood by analyzing the situation in Thailand, which is ironically ranked as the world's ninth most papaya producing country (FAOSTAT, 2013; http://faostat.fao.org/). Angyurekul and Tugsinavisuth (2003), who analyzed the Thai papaya industry during the period 1988–2001, recognized PRSV as the most important threat to Thai papaya industry and emphasized the importance of the development of PRSV-resistant papaya varieties to save the industry. The elite papaya cultivars cultivated in Thailand, Khak Dum and Khak Nuan, which yield red-fleshed elongated fruits, are extremely susceptible to PRSV.

In Thailand, PRSV was first detected at Khon Kaen province, the Northeast region of Thailand in 1975 (Srisomchai, 1975) and spread over the Northeast region in 1981. During 1980s, PRSV rapidly dispersed through the central region of the country, which is the major papaya plantation area, and seriously decreased papaya production nationwide (**Figure 4**). Plantation and production of papaya decreased by more than a half between 1997 and 2006 and the declining trend is continuing to date. Papaya growers decrease the extent of damage of PRSV by shifting cultivation to the new isolated areas, a practice economically unviable. In the Northeast region of Thailand, papaya is cultivated as a backyard crop grown by subsistence farmers.

The magnitude of PRSV devastation of papaya production can be understood by the reported extremely poor papaya productivity in Thailand. More than 98% of papaya produced in Thailand is consumed in the country. In 2010, Thailand produced as low as 211 594 ton of papaya, barely meeting the domestic demand and exporting a paltry 630 ton of papaya (FAOSTAT, 2013; http://faostat.fao.org/). The decrease in yield and insufficient supply of papaya has led to the import of papaya from neighboring countries (Napasintuwong and

Figure 4 Devastation of the disease caused by *Papaya ringspot virus* (PRSV) in Nakhon Pathom, a Province of Central Thailand. (a) Symptoms of ringspots on papaya fruit. (b) Oily streaks on stem. (c) Mosaic and distortion on leaves. (d) A papaya orchard completely destroyed by the ringspot disease. The grower (right front) explaining his pain and sorrow to the experts: Dr. Wichai Kositrana, Kasesart University, Thailand (third from left), Dr. Neal Van Alfen, University of California, Davis (second from left), and Dr. William Lucas, University of California, Davis (first from left).

Traxler, 2009). The quantum of import of papaya, which was started in 2007 in an insignificant quantity, is gradually increasing; in the year 2010, Thailand imported 329 ton of papaya (FAOSTAT, 2013; http://faostat.fao.org/).

Development of Coat Protein-Transgenic Papaya in Thailand

Several strategies to manage PRSV in Thailand include the attempted eradication of infected papaya during 1979–81, in the Northeastern part of Thailand. This program advocated by the Department of Agricultural Extension (DAE), Ministry of Agriculture and Cooperatives (MOAC), was unsuccessful in combating PRSV. The healthy papaya seedlings supplied to the villagers for replacement were infected by PRSV within a short period after planting. Moreover, small-scale papaya growers and subsistence farmers growing papaya as a backyard crop declined to destroy their infected papaya trees, especially during the fruit-bearing stage.

In 1987, collaboration between the Thailand DAE, MOAC, and Cornell University, supported by USAID, was set up to control PRSV by adopting cross-protection and developing PRSV-tolerant papaya cultivars. Cross-protection (also see Section Effective Control of *Papaya Ringspot Virus* by Netting) using nitrous acid-induced attenuated PRSV strain HA5-1 (Yeh and Gonsalves, 1984) and naturally occurring mild strains, including PRV-F1 (Kositratana *et al.*, 1991), was inadequate for sustainable PRSV control in the field trials (Sakuanrungsirikul *et al.*, 2005) and labor-intensive, especially when farmers select hermaphrodite plants after inoculating all seedlings during their early sexually monomorphic stage. In conventional breeding program for tolerant hybrid cultivars (also see Section Control of *Papaya Ringspot Virus* by Cross-Protection), the Thai cultivar Khak Dum was crossed with the tolerant Florida cultivar Cariflora (Conover *et al.*, 1986). However, the resultant three lines, Tha Pra 1, 2, and 3, were insufficiently tolerant to manage PRSV, and they yielded unmarketable fruits (Sakuanrungsirikul *et al.*, 2005).

In Thailand, three independent research groups, (1) Department of Agriculture (DOA), MOAC, in collaboration with Dr. Dennis Gonsalves of Cornell University under the Northeast Rainfed Agricultural Development (NERAD) Project at Northeast Regional Office of Agriculture (NEROA), (2) National Center for Genetic Engineering and Biotechnology (BIOTEC) in collaboration with Kasetsart University, and (3) Institute of Molecular Biology and Genetics (IMBG), Mahidol

University, developed PRSV-resistant transgenic papaya using CP genes of different geographical PRSV strains of Thailand (Warin *et al.*, 2003; Sakuanrungsirikul *et al.*, 2005; Kertbundit and Juricek, 2010).

The Delay in Adopting Transgenic Technology Impedes Papaya Production

Since 1999, evaluation of PRSV resistance and Biosafety assessments of these transgenic papaya lines under greenhouse and field conditions have been conducted (Sakuanrungsirikul *et al.*, 2005; Phironrit *et al.*, 2010; Kongsawat *et al.*, 2011; Chusang *et al.*, 2011), though transgenic papaya has not been deregulated in Thailand. Although the sixth National Social and Economic Development Plan of Thailand (1987–1991) emphasized biotechnology as one of the frontier areas of agricultural development, there are self-limiting constraints and inconsistencies that block the process of deregulation essential for avoiding loss of millions of dollars of economic benefits. In Thailand, the BIOTEC, established in 1983, has played an important role in driving Thailand toward becoming the first ASEAN country to draw the biosafety guidelines in June 1992 (Technical Biosafety Committee, 2010). To ensure safety and to prevent unpredictable risks, Thai government amended the 1964 Plant Quarantine Act to strengthen the regulation of GM crops in 1999. On 17 March 2000, 40 transgenic crops (except corn and soybean) were listed as prohibited and banned from importation and commercialization. On 14 October 2003, an additional 49 GM crops were listed as prohibited, however, allowing import of processed products and materials for research purposes. Flavr Savr tomato was the first transgenic crop introduced into Thailand for field testing in 1994. Following permission for field trial in 1996, Bt cotton was expected to be the first transgenic crop to be deregulated and commercialized in Thailand, following required field assessment. However, in October 1999, certain nongovernmental organizations (NGOs) reported that Bt cotton was spreading from Monsanto's approved site to the fields of local farmers. The political pressure from the assembly of the poor forced the Thailand cabinet to declare a moratorium and to ban all field trials of transgenic plants on 3 April 2001, until the biosafety law is enacted. Only small secluded fields of transgenic papaya at DOA research station, Kasetsart University and Mahidol University were allowed to continue under the IBC regulations. In July 2004, Greenpeace Organization alleged transgenic papaya seed contamination of Khak Dum and Tha Pra cultivar seeds distributed by DOA as an intentional act of DOA and demanded Thai government to immediately destroy all papaya seedlings, trees, fruits, and seeds at the research station to prevent further spread of contamination. Consequently, a series of political, governmental, and legal developments came into force leading to a prime ministerial order to destroy all field trials in the country, a cabinet decision to place a moratorium on all confined field trials in Thailand. Despite the opposition to GM technology by activists, some scientists strongly believe that GM crops have great potential to solve energy and food security problems. As a result, the Thai Cabinet on 25 December 2007 revoked the field trial ban of GM crops, however, with stringent regulatory conditions.

To date (September 2013), no field trials or commercialization of GM crops is allowed in Thailand due to fear of losing export markets, environmental and health concerns, and seed business takeover by multinational seed companies. Little public information is available on the costs and benefits of GM technology to the Thai economy; clear national policies on research and application of GM crops are yet to be made. Economic evaluation of transgenic crops is essential for the development of appropriate future agricultural biotechnology policies. Ex-ante impact assessment based on scientific data and economic environment of GM papaya adoption in Thailand estimated that total economic surplus in the range of US$ 650 million to 1.5 billion would be generated within the first 10 years of adoption. Benefits from GM papaya adoption would accrue primarily to small-scale papaya farmers and also would accrue even with the loss of export markets (Napasintuwong and Traxler, 2009). The delay in adopting transgenic technology in Thailand reflects the lack of comprehensive biosafety laws, public skepticism concerning transgenic plants, the lack of trust in the capability to regulate biosafety, and the effectiveness of the anti GM groups. This situation dissuades Thai researchers from using modern biotechnology to improve the quality and quantity of crop and food productions in Thailand.

Current Advances on Papaya Biotechnology

The government of Taiwan follows the European trend, and has not approved growing any GM crops on the island yet. However, researches for the development of CP transgenic resistance and authorized field tests under isolated conditions have been strongly supported by the government in the past two decades. The GM crop policy deadlock, however, with government's support for the development, analysis, and improvement of transgenic papaya, proves to be a boon in disguise to improve papaya transgenic technology. The basic studies to understand the complexity of potyviruses infecting papaya and the repeated field tests of CP transgenic papaya for more than 10 years helped the advancement of GM technology toward the development of aforementioned single and double resistances to PRSV and PRSV-PLDMV, respectively; and super resistance to PRSV super strains. The findings in concert with the information of integrated genetic map and genome sequence of papaya from the University of Hawaii (Ming *et al.*, 2008; Yu *et al.*, 2009) helped the development of new skills such as marker-assisted molecular breeding for fixation of hermaphrodite sex and fruit quality traits.

In papaya cultivation, because the hermaphrodite fruits are commercially desirable, growers normally plant seedlings in numbers far greater than required, and grow them till early flowering stage to identify and exclude less desired female individuals. To avoid this wasteful and labor-intensive practice, micropropagation by tissue culture techniques to mass produce hermaphroditic papaya plants with uniform fruit size and quality have been developed. New transformation strategy (Kung *et al.*, 2010) using somatic embryos (Lin and Yang, 2001) derived from adventitious root tissues of *in vitro* micropropagated shoots of selected hermaphrodite individuals from different varieties can retain desirable sex and

fruit traits in the regenerated virus-resistant T_0 generation, which can be directly applied for commercialization by the micropropagation method, and thus avoid the lengthy post-transformational breeding process.

The molecular markers developed from the flanking sequences of a particular transgene insert can help identify the homozygotic transgene in the seedlings (Fan *et al.*, 2009). This, coupled with the hermaphrodite sex markers, can promptly identify a hermaphroditic progeny carrying a homozygotic transgene. These molecular markers assisted in pyramiding different transgenes conferring single, double, or super resistance to generate elite papaya hybrids with broad-spectrum resistance against different geographical PRSV and PLDMV strains.

Transgene Integration Event-Specific Markers for Fastening the Process of Molecular Breeding

The issues of concerns have been raised on the safety of food from genetically modified organisms (GMOs) and food production (Singh *et al.*, 2006). Various legislations have been applied in different countries for the GM food approval and labeling. According to European Union (EU) regulation (EC) No. 1830/2003, it is required to trace GMO and products derived from GMOs at every stage from production to the distribution chains (European Parliament and Council of European Union, 2003). The regulation in Taiwan for GM crop field tests and the consequent variety rights also require the information of genomic sequences flanking the transgene for every transgenic line. Therefore, characterization of a particular GM crop to provide specific and reliable information for event-specific detection is crucial to assure regulatory compliance and also important to monitor unauthorized GM crop occurrence in markets and plantations. Several approaches have been developed for characterizing the inserted transgene and plant genomic DNA sequences flanking T-DNA for identification of a transgenic line (Fan *et al.*, 2009 and references therein). Thus, protocols to ascertain integration of T-DNA in transgenic papaya lines have been developed. Screening and confirmation protocols with appropriate oligonucleotide primers designed from the flanking sequences for transgene integration event-specific characterization have been established (Fan *et al.*, 2009). These protocols are important not only for the regulatory requirement and the intellectual protection of the developed transgenic papaya lines, but also for risk assessment, biosafety assay, and molecular breeding of papaya for crop improvement. At present, these transgene integration event-specific markers are being used for monitoring the transgene genotype status of the parental lines and their progenies during the breeding process for pyramiding different transgenes into a super hybrid hermaphroditic papaya line.

Papaya Sex-Linked DNA Markers and Traits Genes for Sex-Determination and Fruit Quality

Carica papaya is a triecious species comprising individuals of male, hermaphrodite, and female sexes; the plants are diploid ($2n=18$). The male plants are solely pollinators and economically unimportant, and, from farmers' perspective, they are a serious liability. Moreover, the female plants, which produce spherical fruits of thinner flesh with more seeds are commercially less desired than the hermaphrodite plants, which produce pyriform fruits of thicker flesh with lesser seeds. Hence, it is important to develop efficient methods for papaya sex-identification at a very early seedling stage at the nurseries to avoid planting individuals of unwanted and less desired sexes in papaya orchards. This necessitates in-depth studies of papaya genetics and subsequent application of outcomes in papaya cultivation.

Earlier studies on the sex of papaya identified a sex-determining gene represented by three alleles, M, M^h, and m; males (Mm) and hermaphrodites (M^hm) are heterozygous and females (mm) are homozygous recessive (Storey, 1938; Hofmeyr, 1938). MM, M^h M^h, and M M^h are embryonic lethal (Hofmeyr, 1938; Storey, 1938). Hence, a hermaphrodite crossing results in a 2:1 segregation of hermaphrodites to females. Cloning and characterization of the papaya sex-determining and sex-related genes have profound applications in papaya production. Papaya possesses recently evolved sex chromosomes. Papaya Y chromosome has a male-specific region, which has undergone severe recombination suppression and DNA sequence degeneration (Liu *et al.*, 2004; Ming *et al.*, 2007). Ming *et al.* (2007) suggested that two sex-determination genes control the sex-determination: a feminizing (stamen-suppressing) gene determines stamen abortion before or at flower inception, and a masculinizing (carpel-suppressing) gene determines carpel abortion at a later flower developmental stage. Recently Ming and coworkers (Gschwend *et al.*, 2011) constructed two bacterial artificial chromosome (BAC) libraries from papaya male and female genomic DNA.

Identification of reliable molecular markers for papaya sex-identification at the seedling stage will facilitate papaya cultivation and breeding by saving time, space, and labor cost. The papaya sex locus has been genetically mapped to a specific linkage group (Sondur *et al.*, 1996). Several random amplified polymorphic DNA (RAPD) and microsatellite markers linked to papaya sex have been reported (Sondur *et al.*, 1996; Parasnis *et al.*, 1999; Urasaki *et al.*, 2002; Deputy *et al.*, 2002). An RAPD papaya sex-determination marker (PSDM) of 450 bp is present in male and hermaphrodite plants, but absent in female plants (Urasaki *et al.*, 2002). Based on such RAPD-based PSDM sequences, fully specific sequence-characterized amplified region (SCAR) markers can be determined for accurate sex-identification. For instance, the SCAR primers, SCAR T12 and SCAR W11, amplify a hermaphrodite- or male-specific SCAR marker. The primer SCAR T12 in combination with SCAR T1, which amplifies a product regardless of sex type, enables prediction of hermaphrodite plants in a seedling population with an overall accuracy of 99.2% (Deputy *et al.*, 2002).

Ma *et al.* (2004) constructed a high-density genetic map of papaya using 1498 AFLP markers mapping into 12 linkage groups spanning a total genetic length of 3294 cM. The genetic map revealed severe recombination around the sex-determination locus with 225 markers cosegregating with sex types. A sequence-tagged high-density microsatellite genetic map of papaya (Chen *et al.*, 2007) and a physical map of the papaya genome with integrated genetic map and genome sequence (Ming *et al.*, 2008; Yu *et al.*, 2009) have been constructed for comparative structural evolutionary genomics of

papaya. In-depth analyses of high-density genetic maps, detailed physical maps, and full genome sequences and molecular/genetic studies are likely to uncover candidate sex-determining genes and other agriculturally important genes of papaya. Skelton *et al.* (2006) cloned and characterized a lycopene β-cyclase (*lcy-β*) gene, which was later renamed as *lcy-β*1 (Devitt *et al.*, 2010), when a second lycopene b-cyclase gene, *lcy-β*2 (along with *lcy-β*1), was cloned and characterized by Devitt *et al.* (2010) from the red papaya cultivar Tainung. Blas *et al.* (2010) cloned and characterized a papaya chromoplast-specific lycopene β-cyclase, CpCYC-b, from SunUp papaya cultivar. The flesh color of papaya fruit, which is determined by lycopene or β-carotenoids accumulating based on the expression pattern of different lycopene β-cyclase genes (Skelton *et al.*, 2006; Devitt *et al.*, 2010; Blas *et al.*, 2010), is an important quality trait that correlates with nutritional value and consumer preference (Blas *et al.*, 2010).

Genetic Transformation Using Somatic Embryos and Micropropagation of Hermaphroditic Plants of Papaya Cultivars

The fruits from hermaphroditic papaya plants are commercially desirable than female plants, for they contain less seeds and thicker flesh (Yeh *et al.*, 2007). However, the sex and other horticultural and fruit traits of transgenic papaya lines can be determined only after flowering and fruit production. Hence, despite the time and effort spent, only a subpopulation of plants is represented by the hermaphrodite plants that are desirable for their fruit quality.

In general, the breeding programs aiming to incorporate the desired sex and other useful traits into commercial hybrid cultivars of papaya are technically complicated, labor-intensive, and time-consuming. In papaya genetic transformation for micropropagation, somatic embryos derived from premature zygotic embryos are the most commonly used starting materials (Fitch and Manshardt, 1990; Cabrera-Ponce *et al.*, 1995, 1996; Cheng *et al.*, 1996; Cai *et al.*, 1999). Such premature zygotic embryo-derived somatic embryos are considered to be the most effective explants for both biolistic delivery and *Agrobacterium*-mediated transformation. However, the immature zygotic embryos are very difficult to obtain and often affected by seasonal factors.

Hermaphrodite plants can be generated as clonal plants using appropriate tissues from selected hermaphroditic individuals through somatic embryogenesis. As shown by Lin and Yang (2001), the adventitious roots developed from *in vitro* shoots of hermaphroditic individuals can be cultured to induce somatic embryos within four months. Using somatic embryos derived from the adventitious roots of *in vitro* shoots of hermaphroditic individuals as explants, Kung *et al.* (2010) transformed the elite hybrid cultivar 'Tainung No. 2' with a chimeric transgene comprising portions of PRSV and PLDMV CP gene sequences. The selected transgenic hermaphrodite lines confer complete resistance to both PRSV and PLDMV. This strategy was also used to produce transgenic plants of the parental lines of Tainung No. 2 hybrid cultivar, including Thailand and Sunrise (Kung *et al.*, 2010).

To ascertain the hermaphroditic criterion of the obtained transgenic lines during early seedling stage, Kung *et al.* (2010) used the hermaphrodite sex-linked RAPD marker amplifiable by the primers SDP1 and SDP2 (Urasaki *et al.*, 2002). The RAPD marker-predicted transgenic seedlings turned up to be a population, exclusively, of hermaphroditic individuals with floral and fruit phenotypes indistinguishable from those of nontransgenic control plants.

Genetic transformation of somatic embryos derived from the adventitious roots of *in vitro* shoots of hermaphroditic individuals of the elite papaya results in hermaphroditic papaya lines of desired horticultural traits for direct large-scale micropropagation without posttransformation breeding. Compared to the recently generated double-virus resistant papaya lines with female sex regenerated from immature zygotic embryos (Kung *et al.*, 2009), which needed several years to generate hermaphroditic papaya with desired properties via breeding, this new approach (Kung *et al.*, 2010) significantly shortens the time-consuming breeding program.

Pyramiding of Single, Double, and Super Transgenic Resistance in a Commercial Hybrid for Global Application

For broad-spectrum resistance to strains of PRSV and PLDMV, a commercial papaya hybrid Tainung No. 2 is currently being developed by pyramiding the transgenes from the parental lines Thailand and Sunrise carrying various transgenes. The breeding procedure involves (1) selection of transgenic lines with high degrees of resistance to PRSV and PLDMV and (2) fixation of the transgene in parental line as homozygote by selfing of double-virus-resistant papaya line of Thailand and super-PRSV resistant papaya line of Sunrise. As demonstrated recently (Fan *et al.*, 2009), appropriate transgenic event-specific primers are used to monitor the transgene-genotypic status of the parental lines or progenies during breeding and to confirm pyramiding of the transgenes in the final hybrid of new Tainung No. 2. In this way, a new Tanung No. 2 hybrid with broad-spectrum resistance to strains of PLDMV and PRSV can be generated within two years. During the process of pyramiding, appropriate sex-linked markers, as suggested by Urasaki *et al.* (2002), are used to confirm the hermaphroditic nature of the hemizygotic or homozygotic status of each papaya line and its progeny. The development of this super transgenic hybrid papaya should have a great potential for global application for controlling different strains of PRSV and PLDMV in different geographical regions.

Environmental and Food Safety Assessments of Transgenic Papaya and International Trading

Environmental organizations, a section of statesmen, and informed public are conscious of the potential risks associated with GM. Scientific and regulatory authorities are also aware of potential environmental and socio-political risks associated with GM crops. Hence, decision making in favor of cultivation of GM crops and commercial release of GM food and other GM products is tough and requires political will. Safety assessment frameworks have been designed to identify potential environmental and food safety risks before commercial release (König *et al.*, 2004).

The analyses of the transgene insertion sites and flanking genomic DNA in CP transgenic papaya did not predict any allergenic or toxic proteins (Suzuki *et al.*, 2008). Moreover, no ecological effects of transgenic papayas on surrounding soil, microflora and insects, and adjacent nontransgenic papaya plants were found (Sakuanrungsirikul *et al.*, 2005). Consumption of GM papaya does not affect human and livestock health, because GM papaya is relatively free from viral components; when compared to the abundance of viral CP in non-GM papaya (which is in general infected with PRSV), the transgenic CP is expressed at very low levels in the transgenic papaya (Fermín *et al.*, 2011). PRSV CP is heat-labile and degraded in simulated gastric and intestinal conditions (Fuchs and Gonsalves, 2007; Roberts *et al.*, 2008; Fermín *et al.*, 2011). Moreover, PRSV CP does not resemble any known allergenic proteins and is not allergenic by property (Fermín *et al.*, 2011). Powell *et al.* (2010) found that long-term exposure to diets formulated with CP transgenic papaya did not result in any significant effects on intestinal morphology, histology, digestive enzyme activities, and intestinal microflora. Lin *et al.* (2013) evaluated the toxicity effects of the fruits of two backcross transgenic papaya lines and their hybrid line and found that the transgenic CP was rapidly hydrolyzed in SGF and the products were undetectable in organs and gastrointestinal contents in rats. Moreover, a repeated feeding of papaya fruits did not evidence biological or toxicological significance between nontransgenic and backcross transgenic papaya fruits in rats. Tripathi *et al.* (2011) showed that the contents of nutrients, benzyl isothiocyanate, and papain of CP transgenic Rainbow papaya are within the range of those of nontransgenic papaya and that the Rainbow cultivar is substantially similar to the nontransgenic cultivar. With regard to the products of the marker transgenes, the safety of NPTII and GUS proteins in transgenic food and feed products has been widely demonstrated in chronic and subchronic investigations (Gilissen *et al.*, 1998; Miki and McHugh, 2004; Ramessar *et al.*, 2007). Moreover, CP transgenic papayas, also harboring *npt*II and *gus*A transgenes, have been on the US and Canadian markets since the late 1990s and mid-2000s, respectively. No evidence of ill effects is linked to their consumption (Fuchs and Gonsalves, 2007).

In the case of the PTGS-mediated transgenic resistance of the CP transgenic papaya, the untranslatable transgenic CP RNA is destined to be degraded and CP is not synthesized; so, most of the above described concern about transgene-derived PRSV CP does not arise.

Concluding Remarks

The transgenic resistance conferred by the viral CP gene has become the most effective method to prevent papaya from infection by the noxious PRSV. In 1998, the Hawaiian PRSV CP gene transgenic papaya cultivars Rainbow and SunUp were deregulated and granted approval for commercialization, representing the first successful application of transgenic fruit tree in the world. Although the transgenic lines are not resistant to most of the PRSV strains from other different geographical areas, the breakdown of the transgenic resistance to PRSV strains indigenous to Hawaii has not been noticed. This probably due to the fact that Hawaii island is isolated by thousand miles of ocean and the virus strains are quite homogenous. Thus, the GM papaya has saved the papaya industry in Hawaii, without any significant adverse effects to environment and human health during the application for more than a decade. After intensive studies to meet the strict biosafety regulations of Japan, the GM papaya of Hawaii was allowed to be sold in Japanese markets since 2011, representing the first case of GM fruit permitted for international trading. If this successful model of production and trading is accepted by most countries, GM papaya will become one of the important fruits for international markets.

In the case of Taiwan, the situation is more complicated. The government follows the European trend, and does not approve the growth of any GM crops on the island yet. However, the research and field tests under isolated conditions have been strongly supported by the government in the past two decades. Our intensive field trials and laboratory investigations of potyviruses infecting papaya triggered advancement of GM technology toward the development of single, double, and super resistances to PRSV, PRSV/PLDMV, and super-PRSV strains, respectively. Also, the micropropagation tissue culture technique, the somatic embryos transformation method, and marker-assistance molecular breeding for fixation of hermaphrodite and transgenes represent the most advanced levels for papaya biotechnological research. However, the national regulations which do not provide the necessary support for the utilization of GM papaya, in fact, hamper the practical application of GM papaya to transform papaya industry. Although the netting system is a very effective way to prevent PSRV infection, the high cost, inferior fruit quality, and environmental hazards make this artificial cultivation system unacceptable for ecologically conscious people.

However, unexpected breakdowns of single-virus resistance of PRSV CP transgenic lines by PLDMV and double-virus resistance of PRSV-PLDMV CP transgenic lines by super strains of PRSV were encountered. The breakdown of the transgenic resistance by the super virulent strain PRSV 5–19 due to its stronger gene-silencing suppression ability of the HC-Pro, which can shut off PTGS and abort the transgenic resistance completely, does not result from the divergence between viral CP gene and the transgene. Thus, the application of CP transgenic resistance based on the mechanism of RNA silencing may select out super strains that contain a stronger silencing suppressor for more virulent infection. These super strains not only threaten the transgenic papaya, but also may wipe out other nontransgenic papaya or other cucurbitaceous crops. Thus, carefully monitoring the dynamic change of virus population after the application of a GM crop is important to prevent the risk of the selection, the emergence, and the spread of such super virulent strains.

In Thailand, although the CP transgenic papaya lines resistant to PRSV have been developed, hope for deregulation of GM papaya is bleak and politically mired. The strong campaign by anti GM crop groups such as Greenpeace Organization strongly influences the policy and regulation for GM field tests and approval. Most of the research on GM papaya is either stalled or inhibited. The production and plantation

areas of papaya are declining, and the sufferings of the growers from PRSV devastation never get eased. This makes a country with excellent potential for surplus production and profitable export of papaya to import the same. In this situation, the benefits of GM papaya are not appreciated and the costs and devastation of PRSV prevail to a worst condition.

To disarm the stronger gene-silencing suppression ability of the invading super strain, new transgenic papaya lines carrying the untranslatable sequences targeting HC-Pro gene have been developed by *Agrobacterium*-mediated transformation of papaya somatic embryos from selected hermaphrodite individuals of elite hybrid cultivars and their parental lines. Several transgenic lines show high degrees of resistance to the super strain PRSV 5–19 and other severe strains originated from different geographical regions. The recent advances in transformation of somatic embryos derived from the adventitious roots of elite papaya cultivars provide a prompt way to generate transgenic papaya lines with desired horticultural properties and hermaphrodite sex, for direct application or to shorten the time-consuming process of breeding. The molecular markers derived from the flanking sequences of the transgene integration significantly fasten the molecular breeding process for pyramiding of single, double, and super transgenic resistance into a commercial hybrid variety. The pyramided transgenic resistance is expected to have a more durable wide-spectrum resistance to different geographical strains of PRSV and PLDMV and can avoid the selection for super virulent virus strains. These will result in a more sustainable application of GM papaya in different regions of the world.

Glossary

Agribusiness The sector of the economy that is the sequence of interrelated activities made up of genetics and seed stock firms; agricultural input suppliers, agricultural producers, agricultural commodity merchandisers, food processors, food retailers, and food consumers.
Capital structure The mix of debt and equity used by a firm to finance its purchase of assets.
DuPont analysis of profitability A financial management tool that decomposes return on equity into its component parts: operating profit margin, asset turnover, and financial leverage.
Entrepreneurship The capacity and capability to identify new business opportunities and to successfully bring that opportunity to market and generate superior financial performance.
Porter's Five Forces analysis A strategic framework useful for assessing industry structure and profitability that includes industry rivalry, power of buyers, power of suppliers, threat of substitutes, and threat of new entrants.
SWOT analysis A strategic assessment at the firm level that includes an analysis of the firm's internal strengths and weaknesses in addition to the firm's external opportunities and threats.

Introduction

The purpose of this article is to discuss contemporary topics in food and agribusiness research with a focus on a definition of agribusiness, a description of the global agribusiness environment, and a discussion of the roles in managing an agribusiness firm.

Concept of Agribusiness

The agribusiness sector is comprised of interrelated subsectors working in concert to provide goods and services to consumers around the world. With the need to accommodate economic, social, and environmental concerns, organizations and managers in the sector share many of the challenges that exist in other business value chains. However, food is an economic good with distinctive cultural, institutional, and political aspects shaping the economic environment of the sector, the organizational structure of its firms, and the choice set available to its managers. Further the fundamental uncertainties emanating from weather and other sources of variability within biology-based production sectors add to the complexity of management in the sector.

Food and Agribusiness Value Chain and Sectors

As depicted in Figure 1, the sector can be thought of as a sequence of interrelated activities made up of:

- Genetics and seed stock firms
- Input suppliers
- Agricultural producers
- Merchandisers or first handlers
- Processors
- Retailers
- Consumers

This, of course, is a general listing and finer distinctions, for example, separately identifying wholesaling and food service, could be done. Supporting these activities are firms that provide services, financing, and research and development to the sector. Also, as indicated in Figure 1, the sector operates in an international context with substantial levels of both imports and exports.

This perspective of the agribusiness sector is not new (Davis and Goldberg, 1957; Sonka and Hudson, 1989). However, there are important differences between this depiction and many that are traditionally offered. First, the depiction in Figure 1 explicitly includes agricultural production, thus eliminating the artificial exclusion of farming enterprises. A second distinction relates to the inclusion of consumers in the diagram. This recognizes the increasing demand by consumers for new products and the resulting impacts on the production, processing, and distribution of food, fiber, biofuel, and other bio-products. Success in the sector requires an understanding of the needs and desires of consumers in both domestic and world markets.

Distinctive Challenges Faced by Food and Agribusiness Firms

There are at least five distinctive characteristics of the sector:

1. Unique cultural, institutional, and political aspects of food, domestically and internationally,
2. 'Uncertainty' arising from the underlying biologic basis of crop and livestock production,
3. Alternative 'forms of political intervention' across subsectors and nations,
4. Institutional arrangements that place significant portions of the 'technology development process' in the public sector, and
5. Differing 'competitive structures' within the stages of the sector.

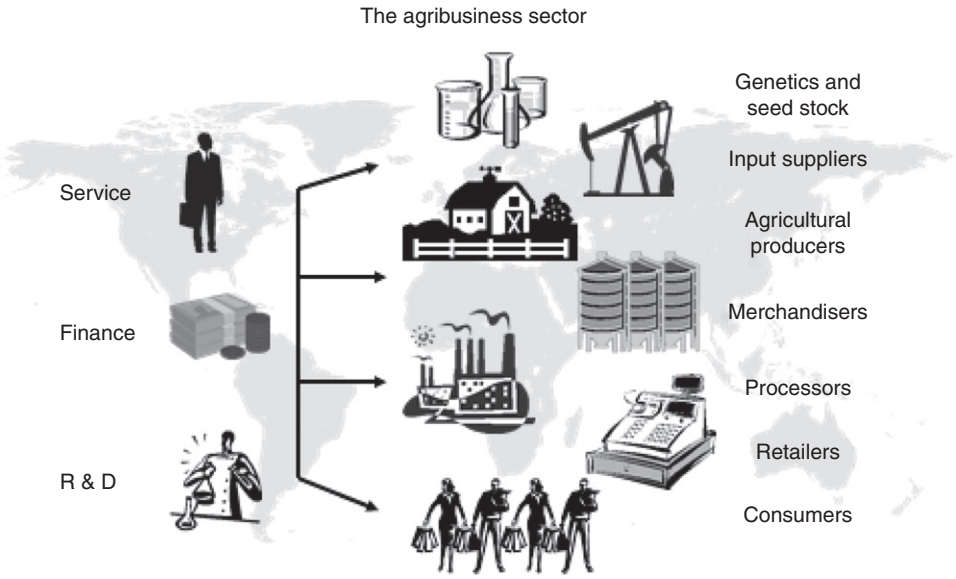

Figure 1 The agribusiness sector. Adapted from Sonka, S.T., Hudson, M.A., 1989. Why agribusiness anyway? Agribusiness 5, 305–314.

These five characteristics suggest the need for targeted managerial skills and knowledge to facilitate effective operation within the sector.

We all understand that food is a necessity for human life. Therefore, assuring adequate amounts of safe, nutritious food (e.g., food security) is a priority for all societies and governments. But food and its consumption are integral parts of the culture of human society. Indeed, anthropologists note that cooking food is one of the actions that uniquely define the human species (Murcott, 1986). Differences across nations and cultures relative to the role of specific foods are critical in understanding the agribusiness sector. For example, although wheat and rice are both food grains, rice in the Japanese culture is far more than just the staple food item that wheat is in the Western nations. The key role of international trade requires that sector managers be aware of these cultural differences.

As evidenced on an increasingly routine basis, the forces of nature (e.g., weather and pests) can overwhelm even the sophisticated technology of modem agriculture. Production, marketing, and financial structures to accommodate normal aspects of 'uncertainty' need to be understood by sector managers. The potential for infrequent but massive deviations also must be appreciated. Plans based on alternative uses of low-priced agricultural commodities, for example, must have contingency options available if the supply of those commodities suddenly is limited. Indeed, strategies for biofuel-based alternatives, developed when commodity prices were low, were severely challenged when food prices sharply increased.

'Political intervention' is a reality of the agribusiness sector. The motivating force for that intervention, however, is not limited to assuring food supplies and maintaining farm income. Issues such as food safety, resource conservation, farm worker safety, and the economic well-being of rural communities are also important. Sometimes seemingly operating at cross-purposes, governmental intervention often is disruptive to operations and markets. Further complications arise because of differing attitudes and forms of intervention internationally.

The potential for major change because of advances in 'technology' seems especially likely within the agribusiness sector. For example, applications of biotechnology both had material market effect and captured media headlines in the past two decades. Application of information technology through precision farming and enormous data sets (known as 'Big Data') may have as pronounced an effect. Globally, major research investigations are pursued in both the private and public sectors. Historically, considerable developmental research has been conducted within public sector institutions and that continues to be the case in developing countries. The management and introduction of new innovations in this sector, therefore, is subject to differing processes than would be the case if developmental research was confined solely to either the private or public sectors.

The agribusiness sector depicted in **Figure 1** is comprised of 'competitive structures' that differ across and within its subsectors. The relatively unique structure of the production sector (large numbers of relatively small units) is widely recognized. At the same time, many agribusiness firms are large and multinational in scope. Organizational structure can have major influences on competition within an industry. Managers within the agribusiness sector must operate within the competitive structure of their subsector while understanding the implications of alternative structures for suppliers and customers.

The five distinctive characteristics just noted do not include several issues normally cited. For example, international trade is not listed because international trade is vitally important in numerous economic sectors. For a manager in the agribusiness sector, however, distinctive features of international trade include cultural attitudes regarding food; the range of political influences; and the potential for sudden supply shocks domestically, among competitors, or within customer nations.

Also noteworthy is that this article proposes that the uniqueness of food in combination with the physical, economic, and social attributes of the agribusiness sector provide important challenges and opportunities for sector managers. This article's focus on food differs from the narrow perspective on farm production with price as the primary measure of performance. Today's agenda does include basic food security for many consumers and nations. However, in other instances that agenda must focus on a consumer who demands a changing variety of food products. Often those products must be attractive to a concerned consumer informed by the media about food safety. Food products must be attractive both in terms of the manner in which they are produced and their long-term effect on human health and the environment.

Global Agribusiness Environment

The agribusiness environment simultaneously is extensively global and intensively local. Trade in agricultural products and the operations of multinational agribusiness suppliers and branded food manufacturers extend around the world. Conversely, even today considerable amounts of agricultural production are originated and consumed in villages and local regions following patterns that have existed for centuries. However, as the world's population increasingly lives in urban settings, the need for effective transportation, processing, and distribution intensifies. National and local government policies and regulations have a strong influence within countries around the world. However, their nature and effect can have markedly differing dimensions. Further the organizational forms and the scale of individual firms often differ markedly between the subsectors that comprise agribusiness. The culmination of these, and other, factors add to the challenge and excitement of managing in the agribusiness sector.

Agribusiness Markets in Developed and Developing Countries

The world economy can be understood as several markets, intercommunicated and linked in different blocks, with totally different dynamics in a much more complex environment.

To simplify, markets can be divided into two major groups: those already developed and mature represented by countries belonging to the European Union, Canada, USA, Japan, and South Korea, for example, and those under development, called emerging economies or countries. Brazil, India, China, Russia, and South Africa (the so-called BRICS) are examples that can be classified in this emerging category as are several other Asian, African, Eastern European, and Latin American economies. These markets differ in important aspects that are summarized in Table 1.

An analysis of this table shows that developed markets are more mature and stable, and have relatively predictable characteristics with very well-established aspects, such as logistics, retail, and institutional environment. This maturity is reflected in the population that tends to search for differentiated products and services, featuring various niches seeking healthy products, environmental and social trends, among others.

Consolidation, Concentration, and Structural Change in Linkages along the Food Value Chain

Changes in the economic environment have incented companies to their activities on core competencies, outsourcing others, and therefore reducing diversification. Concentration

Table 1 Major differences among developed and emerging economies

Developed countries	*Parameter of analysis*	*Emerging countries*
Stable	GDP	Growing
Relatively stable	Population	Growing
Relatively stable	Urbanization of population	Urbanization growing fast and emerging of mega-cities
Mature or declining	Food markets	Sales are booming
Small effect on consumption	Income growth and income distribution	Huge impact on consumption (still a high percentage of income spent on food)
Well educated	Consumer profile	Being educated
More homogenous group	Countries characteristics	Different segments of emerging economies, difficult to aggregate
High quality and sophisticated markets	Quality (food safety) in markets	High level of informal markets and food safety under construction
High percentage of consumption (expenditure) in foodservice	Food service share in food consumption	Smaller participation of expenditure in food service
Quite stable	Retail systems	In transformation
Limited possibility	Expansion of commodity production	High possibility
High sensitivity of population and severe laws, recycling, and consciousness	Environment and preservation issues	Low sensitivity of population and regulation being built
Growing faster	Adoption of biofuels	Low growth
Healthy, veggies, fruits, and organics, among others	Consumption directed to:	Quantity and animal protein
Developed and mature	Logistics and transport systems	Early stage of development, immature
Consolidated, respected, and well known	Institutional environment	Being built with high transaction costs

Source: Adapted from Neves, M.F., 2014. The Future of Food Business, second ed. Singapore: World Scientific, 336 pp.

occurrs in several stages of the food chain participants as suppliers, farmers, food industry, retailers, and foodservice. Concentration and consolidation are rules of the game.

The so-called 'hybrid forms' of supply chain coordination are increasingly replacing open-access markets. As hybrid forms are mostly implemented by contracts, one sees the emergence of collaborative networks based on relationships.

Interorganizational relationships can be formal (based on written contracts) or informal (oral agreements), depending on the institutional environment. Some societies value oral agreements and participants have reputation, and a formal document is not needed to make transactions happen and to guarantee behavior. Other countries need formal documents, and in some countries with weak institutional environments, even these written documents do not have value.

Farms Go beyond Food and Fiber: Energy, Nutraceuticals, and Industrial Products

From a traditional perspective of a farm producing food, recent technology innovations and other advancements are enabling farms to be multiproduct and service suppliers. At least 13 industries increasingly source their raw materials from farms:

1. Food and beverages: to produce human food, including grains, fruits, eggs, vegetables, juices, milk, beef, fibers, and others to an increasing and richer population demanding quantity, quality, procedures, conservation, environment, animal welfare, and others.
2. Feed: food for the animal's growth and development, involving nutrition of larger animals, for pets and others.
3. Fuel: biofuels blending programs, which means fuel coming from the farm using corn, wheat, sugarcane, sugar beet, grasses, residues, and other sources.
4. Pharma-medicine: the growing end-use called 'nutraceuticals,' which means food products together with medicine, it involves producing products that have health benefits, like juice with calcium, lycopene, vitamins, proteins, omegas, and several other merged products.
5. Pharma-cosmetics: products from food/farms that have benefits in terms of beauty, skin, tanning, and other characteristics desired by consumers ('nutricosmetics').
6. Electricity: farm products used as a renewable source of electricity, burning biomass in boilers and generating heat that is transformed into electricity, sold to the power network.
7. Plastics: replacing plastic coming from oil with renewable plastic coming from green and farm materials, like plant-based bottles produced from cane or corn.
8. Environment: farms are being used in the battle against global warming, recovering forests, creek surroundings, rivers, and even benefiting from participation in carbon credit markets.
9. Entertainment/tourism: use of farms and rural lands for tourism, weekend rest for urban families, festivals, educational purposes for kids in schools, hunting, and similar recreational services.
10. Textiles and clothings: natural fibers used to produce textiles and clothes for the fashion industry, like cotton and others.
11. Shoe and leather: leather comes from cattle and other animals.
12. Construction and furniture: wood from planted farms using eucalyptus, compensated woods, and other sources.
13. Paper and packing: materials come from processed farmed wood, producing a pulp that is transformed into paper products.

Uncertainty and Volatility

Uncertainty and volatility could endanger the world's food and agribusiness environment. For example, uncertainty surrounding the outbreaks of foodborne illnesses can have large impacts on the firms that have established a brand reputation for safety. Additional examples of uncertainty are provided in Table 2.

Sustainability and the Triple Bottom Line

Sustainability, broadly defined as 'responsible use of exhaustible energy resources and raw materials' has gained increased awareness around the world. Sustainability has three major dimensions or pillars: the economic dimension (profit), the environmental dimension (planet), and the social dimension (people).

On the economic (profit) front, the major factors to be considered are how companies, networks, and production chains deal with margins, profit, compensation, losses in the chain, communication issues for end-consumers, capital investments and funding for sustainable projects, risk management, technology adoption, and overall strategies to reduce costs and achieve economic sustainability of the business. Without economic sustainability, the other dimensions are difficult to support.

On the environment (planet) front, the major factors to be considered are the impact of the company on the environment, the impact of the company's integrated suppliers, the impact of transport (food miles), packaging (trying always to recycle/reuse/rebuild – using renewable materials and less materials), waste management (less waste; separating and recycling; energy/fertilizers from waste), use of energy, water management (protecting water and adapting best practices), green and environmentally oriented buildings and facilities, carbon emissions/neutralization (carbon footprint), among others.

On the social (people) front, the major factors are working conditions for employees, including the company's suppliers and distributors, health and safety, usage of child labor, working climate, safety equipment, commitment to the local community, facilitate cooperation, smallholder-friendly initiatives, improving local companies' capacity, and promoting product line benefits for consumers, more nutritional and healthy.

Agribusiness Firm Management

Industry-Level Analyses

A firm's strategy can be viewed as how it combines its resources to 'go to market' – to supply products/services to

Table 2 Uncertainties and risks in the business environment

	Examples
Political-legal system	● Risks to democracy in some countries; ● Populist measures of some governments and its impact in social expenditures; ● Terrorists and political attacks using food or other sources; ● Global arming (even atomic) procedures and weapons availability taking to unexpected local or regional wars; ● Riots and other challenging political systems; ● Increase in corruption within political systems; ● Labor laws decreasing work productivity and increasing costs and strikes; ● Growth of illegal crime systems and parallel states (drug cartels, nonlicit trade groups and others); ● Declining support to world's organizations and institutions (e.g., World Bank, ONU, FAO, etc.); and ● Immigration and also migration to urban areas threatening infrastructure.
Economic and natural system	● Fiscal debt crisis in some countries; ● Inflation threats in some economies; ● Not sufficient economic growth mostly in poor and emerging economies pressuring governments; ● Supply chain inefficiencies (poor use of land and other resources); ● Infrastructure collapse; ● Financial systems inefficiencies, failures, and lack of financing capital; ● Controlling diseases spreading among human, animal, or plants; ● Over usage of nonrenewable resources (oil and some fertilizers); ● Water shortages and excess causing droughts and flooding (disasters); ● Temperature changes in some regions, with extreme situations; ● Increasing carbon emissions and its effects over pollution; ● Potable water availability; ● Climate change and other planetary threats; ● Food safety risks due to poor management of food supply chains; ● Natural risks of earthquakes, tsunamis, hurricanes, and other extreme events; and ● The impact of fracking technology and shale gas on production costs and the environment.
Sociocultural system	● Fast changes in consumption behavior; ● Consumer activist movements; ● Environmental movements; ● Nationalistic movements; ● Food security concerns increasing inefficiencies in nonadequate producing areas; ● Food waste concerns; ● Nontolerance in some aggressive religious movements; ● Increase in xenophobic movements; and ● Consumer preferences for credence attributes such as organic, humane, and local production.
Technological system	● Digital systems operation (web-based companies, operational systems, and government systems); ● Data piracy, data frauds, and personal privacy issues; ● Viral communication exposure of individuals, companies, and governments; ● Not controlling new high tech innovations, such as genetically modified, nanotech, and others that may get out of control; and ● Traceability of food products from the farm to the final consumer.

Source: Adapted from Neves, M.F., 2014. The Future of Food Business, second ed. Singapore: World Scientific, 336 pp.

customers. Developing a successful strategy requires thorough assessment of the market forces the firm faces as well as the internal competencies and capabilities of the firm. The market assessment will include evaluation of the overall business/economic conditions, competitor actions and positions, and customer expectations using appropriate analytical framework such as Five Forces models and value chain analysis.

Value chain analysis

Value chain analysis assists in understanding the linkages among activities and processes (and thus stages) from initiation of economic activity to create a product or service to the eventual provision of that product/service to the final consumer/user. Boehlje (1999) identifies six critical dimensions of a value chain reaching from (1) the processes and activities that create the products or services demanded by consumers or end users, (2) the product flow features, (3) the financial flows, (4) the information flows across the chain, (5) the incentive systems to reward performance and share risks, and (6) the governance and coordination systems.

Agribusiness value chain for food could be described as two chains that become one at the consumer end (Figure 2). One value chain follows plants and plant products, and another chain follows animals and animal products. These two chains blend into one chain at the processing and retailing stages of the chain. Value chains can be as simple as five

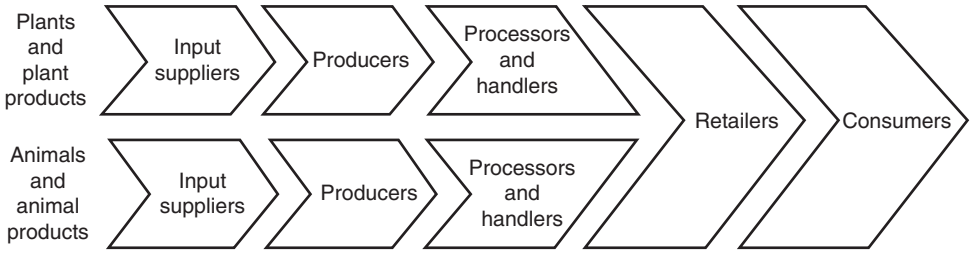

Figure 2 Value chain for plants, animals, and their products.

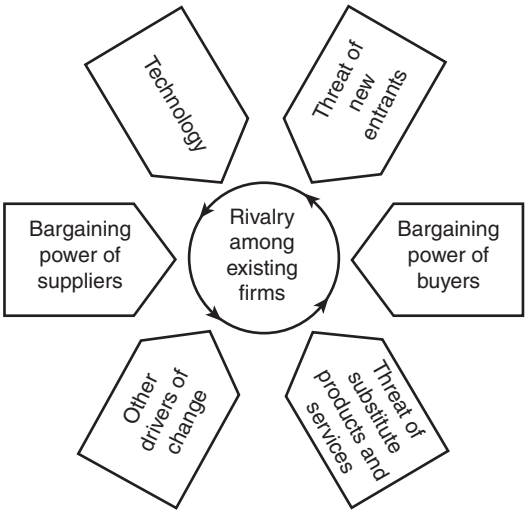

Figure 3 Porter's augmented Five Forces model.

stages: (1) input suppliers; (2) producers; (3) processors and handlers; (4) retailers, and (5) consumers.

Value chain analyses are useful to analyze the structural changes that come along with increased interdependencies of two or more related value chains. For example, due to the application of similar technologies in different sectors (e.g., biotechnology); formerly distinct, value chains are becoming increasingly interlinked and interdependent. Value chain analyses can be used to understand how complexity increases, who will hold the needed competences, how and why vertical integration will occur, and what is needed for successfully managing systemic innovations that affect multiple steps of the supply chain.

Porter's Five Forces

Michael Porter's Five Forces analyses framework is useful to assess industry structure and competitive landscape (Figure 3). Two additional forces affecting competition have been added to Porter's model adding an external dynamic: (1) technology and (2) other drivers of change.

Rivalry among established firms: The level of rivalry within an industry can depend, in large part, on the number of firms, demand conditions, and exit barriers. Owing to the number of firms involved, many agricultural industries are often described as perfectly competitive – as opposed to monopolistic competition, oligopoly, or monopoly. However, government regulation and intervention, as well as the size and dominance of a few firms, can provide different degrees of perfect competition.

Bargaining power of suppliers: Suppliers have power if they are more concentrated than their buyers, do not receive a high percentage of their revenues from one industry, have customers with high switching costs to change suppliers, have a differentiated product, have a product with no substitutes, through either real differences or patent protection, or could integrate forward into additional stages in the value chain.

Bargaining power of buyers: Fewer buyers mean they have greater power. If sellers cannot easily ship their products to other markets, or they do not have price information from other markets, local buyers can have considerable power even though the total number of buyers is large in the wider market. In ways similar to suppliers, buyers have power if they are few in number or a few buy a large percentage of the product in the market, products are undifferentiated commodities, or buyers could integrate backwards in the value chain. Buyers will also bargain harder if the product constitutes a major portion of the buyer's total costs, or if the product has little effect on the quality of the buyer's product or other costs.

Substitute products and services: Substitute products limit the price that producers can seek or ask for without losing customers to those substitutes. Competitive pressure comes from the attempts of the producers of the substitutes to win buyers to their products. The advertising campaigns of the pork, beef, and poultry industries are an obvious example of the competitive pressures due to substitute animal products; each industry feels forced to advertise to keep customers, and cannot charge as much as they would like without pushing their customers into buying other products.

Threat of new entrants: If the costs for new firms entering into an existing industry are sufficiently low, the threat alone may limit the price dominating firms charge to the users. In agribusiness, many subsectors have large initial investments. For example, machinery manufacturing requires large investments in factories to achieve scale economies. The large investments serve as a barrier to entry for new machinery manufacturing companies. Further down the value chain closer to the consumer, established firms invest in branding to create barriers to entry and limit the threat of potential entrants.

Technology: Changes in technology can have a large impact on the production of and demand for a service or product of a firm. The risk from technological change depends on the size and the role of technology in the industry, as well as the speed of technical change. Advances in technology can be disruptive; they can cause leaps that leave users of old technology far

behind. New technology can alter not only the efficiency and cost of the production process, but also the actual products and services offered and demanded by others in the value chain. New chains may be created due to a new technology in communication as well as in products and services.

Other drivers of change: Other drivers of change include changes in government policy and regulations, changes in international trade agreements, demographic changes, and other factors not included in the first six forces. Competitive pressure comes from differing abilities of firms to respond and adapt to these changes. The impact of these forces depends on the scope of the change, the speed at which change is anticipated or actually felt, and the depth and breadth of the responses needed to adapt to these changes.

Market structure and structural change

Useful conceptual frameworks that help understand and explain the structural changes (consolidation, vertical integration, and changes in the vertical and horizontal boundaries of the firms) in agribusiness include: (1) industrial organization and structure, conduct, and performance analysis; (2) transaction cost economies; (3) negotiation/power and trust; (4) strategic management; and (5) risk sharing.

Industrial organization and structure, conduct, performance analyses: One common paradigm used to understand and analyze the competitive characteristics of markets and the firms in those markets is the Structure, Conduct, Performance paradigm. 'Market Structure' refers to the competitive nature of the market. It is characterized at one extreme by many firms of similar size and similar information about market conditions including supply, demand, and prices, which is described as perfect competition; at the other extreme is only one firm with unique information that is a monopoly; or something between these extremes with few firms of different size and information/characteristics, which is described as an oligopoly or monopolistic competition market structure.

As to *conduct*, the prime focus is that of pricing behavior and pricing power. In perfect competition markets, firms have no pricing power. They are price takers with no one firm having the ability to set prices higher than their competitors and continue to sell their product. In a pure monopoly, the firm has no competition and thus it has the power to set high prices without any concern that competitors will take some of the market by charging lower prices. Firms in oligopolistic and monopolistic competition markets have some pricing power depending on the size, information access, and other characteristics of their competitors, and thus have some power to set prices without losing significant market share.

Performance is measured primarily by profits. Perfect competition markets, profits as measured by returns above all costs are zero or minimal because firms will expand output or continue to produce as long as they cover all costs, and no firm has the power to set prices above those costs without losing sales to their competitors. In a monopoly, the firm can generate profits well in excess of costs because of their pricing power, and they do not face the market discipline and competitive pressure to control costs, so monopolies typically have excess profits and may also have higher costs and relatively inefficient operations. Because of the opportunity for a monopoly firm to charge higher prices and extract excess profits from their customers, such behavior is restricted or regulated by antitrust and other laws and regulations. Oligopoly and monopolistic competition industries have modest 'pure profits' (returns above total costs) depending on how competitors respond to each other's pricing or output decisions.

Transaction cost of economics: The concepts of transaction costs and principal-agent theory as conceived by Coase (1937) and expanded by Williamson (1979) and others indicate that structure in terms of the form of vertical linkages or governance in an economic system depends not only on economies of size and scope, but also on costs incurred in completing transactions using various governance structures. Furthermore, these costs and the performance of various governance structures depend in part on the incentives and relationships between the transacting parties in the system: the principal and the agent. Under various conditions, the agent may exhibit shirking behavior (i.e., not performing expected tasks) or moral hazard behavior (i.e., the incentives are so perverse as to encourage behavior by the agent and results that are not consistent with, or valued by, the other party to the transaction, viz. the principal).

Negotiation, power, and trust: More hierarchical governance structures are replacing markets as the coordination mechanism in the agrifood industries. In such systems, negotiation strategy and skill, power, conflict resolution, trust, and performance monitoring and enforcement become central to effective and efficient functioning of the economic system and the sharing of risks and rewards in the system.

Strategic management: strategic management arguments emphasize various approaches that firms must adopt to develop a strategic competitive advantage and to consider in the make or buy decision. In general, the arguments are that competitive advantage is driven by: (a) internal considerations of costs, technology, risks, and financial and managerial resources; and (b) external competitive considerations of synergies, differentiation, and market power and positioning (Harrigan, 1988). The dynamic capabilities approach offers a framework to mitigate changes in the business climate and renew a firm's resources for a sustained competitive advantage in fast changing unstable environments such as those that characterize the agrifood sector (Teece *et al.*, 1997). In fact, given an increasingly turbulent business environment, there are reasons to question the basic concept of a sustainable competitive advantage and replace it with a rather 'temporary' competitive advantage.

Risk sharing: Apgar (2007) argues that value chain partners are critical sources of risk and uncertainty, and they can also provide the potential to mitigate risks and capture opportunities that result from uncertainty. Given the difficulty of establishing sustainable risk/reward sharing arrangements, it is not uncommon for one firm in the chain to become the chain 'captain.' The chain manager or 'captain' may choose to become the residual claimant on profits from the chain as well as assuming a major share of risk, or to share a greater fraction of the profits while shifting more of the risk to the other participants. Failure to find a risk-/reward-sharing arrangement that provides appropriate incentives and is perceived as fair encourages ownership integration of stages by one firm.

Gray and Boehlje (2005) suggests that, in general most tightly aligned supply chains that seek to share risk and

rewards among participants will be increasingly dominated by larger firms at both the buyer and supplier level – leading to more consolidation, particularly at the production end of those industries.

Firm Strategy

Agribusiness firms can employ a number of concepts and tools to craft the best 'fit' between their strengths and the current and future needs of the market. These efforts focus on resources, competencies, and capabilities that create a sustainable competitive advantage, contributing to superior financial performance and mitigating risk from changing market conditions.

SWOT analyses and the value plate

Strategic assessment at the firm level invariably includes analysis of the firm's strengths, weaknesses, opportunities, and threats (SWOT). The opportunities and threats components of the analysis can be directly derived from an effective industry analysis. Although the strength and weakness elements are internally focused, this analysis must consider market and consumer needs and competitor capabilities. In assessing skills and assets, it is critical to candidly evaluate their relevance relative to the following questions (Aaker 1995):

- Why are successful (unsuccessful) firms successful (unsuccessful)?
- What are the key customer motivations?
- What are the large cost components?
- What are the industry mobility barriers?
- Which components of the firm's value chain can create competitive advantage?

Across the sector, assets essential to be successful vary widely. For example, scale and low cost are critical for established grain merchants whereas differentiation and access to specialize skills are critical for high-tech startups. Motivations differ between the farmer and the consumer as customer. Access to safe, affordable food is the need for large segments of the world's population but those characteristics are taken for granted among higher income consumers. Focusing on cost reduction is an important managerial emphasis, especially if the cost component being addressed is substantial. Mobility barriers (both entry and exit) are important because they can indicate the speed at which current and potential competitors can execute strategically.

Assessing capabilities requires detailed examination of the firm and its operations. The internal value chain (or value plate) is a useful tool in this process (Porter). In Figure 4, the firm's primary activities are indicated by the vertical sections within its lower portion. Supporting activities within the firm are represented by the rows across the figure's upper segment. The very right-most section, labeled margin, indicates the goal of profitable operations. It is critically important to recognize that one firm's value plate is linked to its suppliers' value plates and to its customers' value plates.

The importance of each component differs significantly within the sector. Service is critically important in the farm equipment sector whereas inbound logistics is a major success determinant for food processors. Although vastly different in orientation, technology development is a continuous challenge for biotechnology-based input manufacturers and for branded food companies.

The effective use of the skills and assets of agribusiness firms, relative to their competitors, determines the size of the margin component of the value plate. Efforts to increase the margin have traditionally emphasized enhancing efficiency (shrinking the cost components) or increasing revenues (growing the size of the plate). Especially in recent years, outsourcing of support activities has been an important tactic to reduce costs. Aggressive implementation of information technologies has occurred both in the support segment and in the operational components of the primary activities.

Value creation and capture

Value creation, providing goods and services that earn revenues that exceed the cost of doing so, is an elemental reason for a firm to exist. As detailed by Schumpeter (1942), competitive economies rely on market entry and the creative destruction of innovation to shift value to consumers. Value

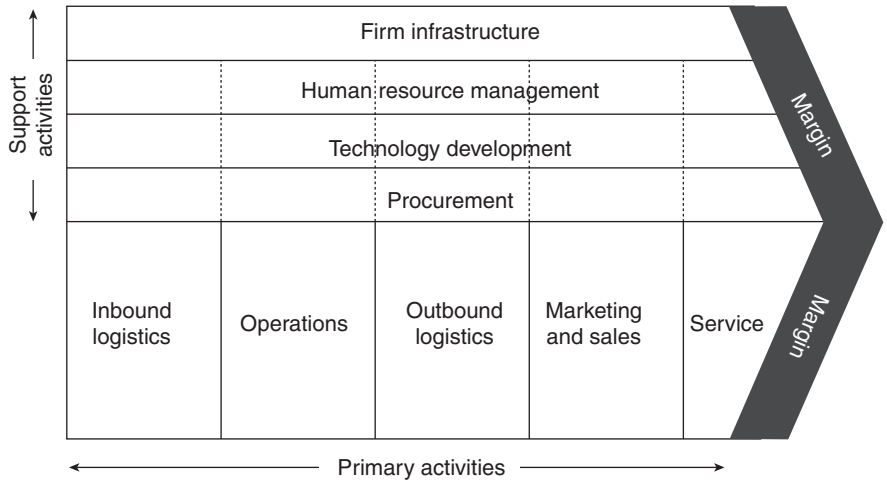

Figure 4 The value plate.

capture emphasizes the extent to which firms, over time, can retain value for their shareholders.

Although value is measurable in financial terms, in today's economy the factors that drive value creation, innovation, people, ideas, and brands, are increasingly intangible in nature. Advances in the capabilities and use of information and communication technologies (ICT) and of science throughout the economy have shifted competitive dynamics, increased the pace of change, and altered the sustaining value of skills and assets. In addition to physical sources of advantage, a long list of categories of intangible assets have advanced in importance, such as technology, innovation, intellectual property, alliances, management capabilities, employee relations, customer relations, community relations, and brand value. As a result, value capture often involves sharing across multiple firms in the value chain.

Agribusiness managers have been adept at integrating science-based innovations as well as ICT-based advances. The future dynamics of the sector are particularly intriguing because successful innovations will need to excel within the 'cyber-physical' context that characterizes operations and markets within agribusiness. Although the advance of cell-phone use has been a recent feature in developing nations, agricultural production (fruits, vegetables, grain, and livestock) still needs to move from rural to urban areas. Unfortunately that process is all too often hampered by inadequate physical infrastructure. Intangible drivers of value creation and capture will be a feature of change within the global agribusiness sector. However, the most substantial gains will accrue to the successful implementation of those drivers in the physical reality of the sector.

Growth

For long-run success, growth is a necessary consideration for the agribusiness manager. Growth introduces vitality into an organization. Further, competitors can be expected to attack the weaker product offerings of the firm. Therefore, growth in some dimension is almost always necessary just to stay even. Although profitable growth is a key managerial focus, sustained profitable growth has proven difficult to achieve – with an estimate that 90% of companies worldwide failed to achieve sustained profitable growth in recent years (Zook, 2010).

Typically, approaches to growth are categorized along the following dimensions:

- Growth in existing product markets
- Product development
- Market development
- Diversification (either in related or unrelated markets)

Bain and Company (Zook, 2010) extends this framework in the context of 'profit from the core,' where successful growth strategies are found to:

- Reach full potential in the core business,
- expand into logical adjacent businesses surrounding the core, and
- preemptively redefine the core business in response to market turbulence.

A recent case study of the Center for Food and Agricultural Business at Purdue University highlights successful firm growth within the sector (Sonka, 2011). JBS United is a diversified mid-sized agribusiness firm, known for its use of R&D to drive innovation that fosters success for its customers. Since its establishment in 1956, it has been headquartered in Sheridan, Indiana. However, its products are employed in animal agriculture throughout the world. In 2010, its sales exceeded US$450 million. As shown in Figure 5, growth has been a constant feature in the firm's history.

In 1956, John Swisher decided to become an entrepreneur and with two colleagues started the firm that has grown into today's JBS United. They chose to initially focus on providing feed for one species, swine, as it would be too difficult to provide high-quality products across species.

Based on the value delivered to its customers, the JBS United firm grew through expansion of market share in its original geography. Over time, friendly acquisitions expanded the market scope for the firm to extend across the Midwest. At the same time, value chain expansion occurred as the firm expanded its farming operations to support applied research and expanded into grain procurement to support its feed milling operations. The acquisition and geography expansion led to entry into dairy nutrition.

Recognizing the dynamic growth opportunities for animal protein globally, JBS United entered the swine nutrition market in the Philippines in the mid-1980s, which was followed

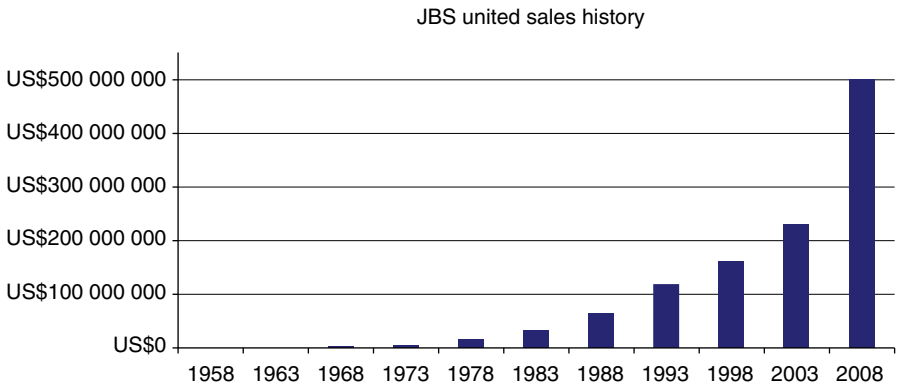

Figure 5 Growth of sales at JBS United, 1956–2008.

by expansion in Southeast Asia and then Central and South America. Since 2000, the firm has participated in successful joint ventures in China, the world's largest pork-producing sector.

Relatively early in the company's evolution, its management team recognized that employing an effective, applied R&D capability would be a key enabler to achieve its market philosophy.

Today, JBS United has an extensive R&D system serving animal agriculture. Research and development capabilities and their value led to establishing the Emerging Technologies Division within JBS United. The division's overriding goal is to advance and develop technologies that will better serve customers and environmental needs worldwide.

Both swine and poultry need phosphorous for bone and muscle development, however, only 20–30% of phosphorus in feed grains is digested. In collaboration with university researchers and by employing its internal capabilities, JBS United brings products to market to dramatically improve the proportion of phosphorous digested. This reduces both costs for the producer and the environmental impact of animal production. Additional products are being developed through joint ventures, which again build on advances in basic science.

The JBS United experience demonstrates the importance of long-term growth for firms in the agribusiness sector. This experience illustrates growth through existing product markets, product and market development, and related diversification. Further it documents that aggressive expansion from the core is possible for small- and medium-sized agribusiness firms.

Marketing

Marketing is one of the most important activities for food and agribusiness companies. Marketing is the relationship development, or the 'contract building' process with possible customers. Successful companies are the ones 'driven by demand,' or companies that pay attention, innovate, and build strong and stable relationships with customers.

Perreault *et al.* (1997) state that if the majority of people, including managers, were forced to define marketing they would say it means 'sales' or 'advertisement.' This answer is not completely true. Sales and advertisement are just two parts of a broader set of marketing strategies. Thus, marketing is defined as "a social and managerial process by which individuals and groups obtain what they need and want through the creation, offer and trade of products and values with others (Kotler, 1997)." Thus, it is a process that aims at satisfying the needs of the customers through trade.

Marketing activities can be divided into two blocks: understanding food and agribusiness customers and performing to meet customers' needs and wants. Understanding the food and agribusiness customers requires firms to assess the needs of the final consumers and intermediaries through a research process. The firms analyze the behavior of consumers to gauge their needs and wants. The firms also scan the macroenvironment (political-legal, economic, natural, sociocultural, and technological) to anticipate changes. The firms also react to competitors' moves in the market. The goal is to identify opportunities to create additional value for customers. The firms will choose among these opportunities based on which consumer market segments the company targets.

Performing is the action the firm takes based on its understanding. Firms offer products that are differentiated from competitors' products. The firms also use the information to generate new and adapt to existing products, brands, and packages to satisfy consumer needs. Firms price the innovative offerings to capture the value created. Firms also implement distribution strategies ensuring products are available to customers at appropriate times and conveniently. Firms communicate the additional value created through advertisements, publicity, and other tools. Now these major marketing performing decisions in food and agribusiness will be addressed.

Performing via product, services, packaging, and brands

Products represent the group of attributes, functions, and benefits that consumers buy. Goods, services, packages, brands, and ideas compose a product, forming a company's offer, trying to meet successfully a consumer need (Perreault *et al.*, 2010; Kotler, 1997). According to Garvin (1987), for an offer to be perceived as 'high quality' by the consumer, the following factors must be considered:

- Performance: refers to the product's capacity of doing well as per expectations;
- Characteristics: concerns the number and complexity of characteristics that differentiate the product;
- Reliability: reflects the possibility of a product failing within a certain time frame;
- Conformity: degree to which the design and operational characteristics of the product comply with preestablished standards;
- Durability: involves the time frame it takes to be replaced;
- Rendered services: development, quickness, and effectiveness of the offered services before, during, and after the purchase;
- Aesthetics: the design, the color, the product's taste, and other more subjective aspects;
- Quality perception: reputation, product, or brand perceived image.

A product, often, comes with a brand. According to the American Marketing Association (AMA) a brand is a name, term, symbol/sign, or a combination of all these, which is associated with different products or services of a specific company. Customers use brands as sources of information, simplifying choices and reducing acquisition risks. They capture beliefs about the attributes and general image of the product among the clients. Manufacturers are more and more interested in selling new products under the protection of well-established brand names, familiar to consumers, increasing their acceptability (Iacobucci, 2001).

Brands allow customers to associate functionalities, images, and experiences. In a competitive market, products become more uniform; therefore, brands evolve to offer differentiated value. The success of the brand depends on associations made only in the customers' minds (**Figure 6**).

Packaging is also an important decision in the product offering. Technological improvements in packaging have made it possible to extend the shelf life of food products. Other

Figure 6 Example logos of food and agribusiness firms.

packaging has enabled consumption on the move, which can alleviate time pressures for the consumer. Innovative packaging has also addressed challenges associated with the negative impact on the environment. Renewable sources of packaging are gaining attention, such as plastics made from cane and corn.

Performing via price

Price can be defined as a relationship that indicates the amount necessary to acquire a given quantity of goods or services (Lambin, 2000). Although other variables of the marketing mix have become important recently, price still remains one of the fundamental elements in setting market share and profitability in companies. Price is also one of the most flexible elements. It can be altered quickly, unlike the other components, such as altering a product or a commitment with a distribution channel.

Even with such an importance, many companies do not set prices well. According to Kotler (1997), the most common errors are: prices overly oriented to costs, prices do not have frequent enough revision to capture market changes, and the price setting does not depend on the rest of the marketing mix and variation not according to different product items, market segments, and purchase occasions. With the information widely available for consumers via the internet, pricing strategies have become much more important and sophisticated.

Food prices are a very sensitive issue, and commodities face huge price variations. For lower income populations, the percent of their income expended on food is higher. Thus, price increases attract substantial media and consumer attention.

Performing via distribution channels (wholesalers, retailers, and logistic operators)

According to Stern *et al.* (1996), distribution channels are a group of interdependent organizations (wholesalers, retailers, and logistic operators) involved in the process of making the company's products or services available for use by customers. The emphasis is on how to plan, organize, and control alliances between institutions, agencies, and internal capabilities in companies. When dealing with channels, it is important to:

- Analyze channels for the company's products and seek new channels, defining distribution objectives, such as: market presence, type and number of points of sale, services offered, market information, product promotion, and incentives.
- Define opportunities and threats of the current distribution system.
- Define the way of entering into markets, if it will be via franchises, joint ventures or other contractual forms, or even via vertical integration; elaborate national or international contracts with distribution channels.
- Determine the annual distribution budget and implement the plan.

In food, due to perishability and the weight/value ratio of all that is being carried, distribution channels and logistics are very sensitive issues.

Performing via integrated communications

Marketing communication consists of efforts made by a company for the transmission of its information to others, seeking to influence attitudes and behaviors. More specifically, communication strives to tell the target customer segments that the right product is available, at the right price, in the right place (Perreault *et al.*, 2010). All modern organizations, private companies, and nonprofit entities, use different forms of marketing communication to promote their offerings. The communication assists firms in achieving financial and nonfinancial objectives. In setting a communication strategy, the following activities should be done:

- Identify the target public that will receive the communication and develop the desired objectives (brand knowledge, brand memory, and persuasion, among others).
- Define the communication mix that will be used: the advertisement plan, public relations and publicity plan, sales promotion plan, as well as direct marketing actions, and web activities, among others.
- Budget and possibly determine the expected return for these investments, measuring well these activities and their impact.

- It is more than just brands in the store and in advertisements, electronic communication is more pervasive and provides more opportunities for communication. For example, firms maintain their own websites and maintain fan pages on social media websites.

In food and agribusiness, communication is an issue that is receiving more media attention. Because of concerns regarding food marketing, human health, and childhood obesity, regulations in food communications are being considered and in some instances implemented.

Performing via sales force and people

The sales force are the people involved in making sales happen. Increasingly, selling is a team activity involving technical, relationship, and commercial skills. The sales force has an immense potential for raising a company's sales; however, it can ruin the whole marketing planning that was made (Zoltners *et al.*, 2001). These decisions are establishing criteria for operation of the sales force in the market, implementation of the sales force, which will be referenced as 'human resources in sales' topics, how to acquire and maintain a well prepared and motivated sales team and, finally, the ways of control in sales. The products and services offered must be attractive to both the end user and the distribution channel.

In marketing, these five blocks of decisions for performance (product, prices, channels, communications, and sales force) is what a company has to beat its competitors in and succeed in the market place. It is very important to have equilibrium in the five elements in order to build stable relationships with customers, and as a manager, keep pressure over the marketing team because markets and customers change and competitors are willing to win over these customers. This understanding is vital for food and agribusiness companies.

In food and agribusiness, the role of the sales force in crop and livestock input suppliers is a fundamental source of knowledge extension to farmers. Several studies have indicated that a company having a strong marketing orientation (that is, a company driven by demand) has better performance in the market place.

Finance

Firms use finance concepts to measure the efficiency of investments and the profitability of operational decisions. Finance is concerned with the sources and uses of cash in the business and the returns to assets (Brigham and Ehrhardt, 2009). Generally speaking, riskier investments should generate higher expected returns to investment. Thus, when agribusiness firms consider investment opportunities, the cost of financial capital is the benchmark return that the investment must return. Once investments are made, managers of agribusinesses use financial statements (income statement, balance sheet, and cash flow statement) to measure, monitor, and correct operational decisions.

Financial statements, financial metrics, and profitability analyses

There are four key financial statements that serve as the basis for tracing the financial performance of the agribusiness firm: the balance sheet, the income statement, the cash flow statement, and the statement of owners' equity. Each of these documents is typically prepared annually, with quarterly updates provided for at least earnings. Corporations are typically required to share an annual report every year with its shareholders. Nearly always these statements are available electronically from the firm's website in the 'Investor Relations' section. Preparation of these documents is completed using the Generally Accepted Accounting Principles or the International Financial Reporting standards, and is typically verified by an independent accounting firm.

Three of the statements report the operations and flow of cash for a period of time: the income statement, cash flow statement, and statement of owners' equity. The balance sheet is prepared for a particular date, and takes stock of the asset, debt, and equity position of a firm on that day. As such the balance sheet can differ substantially depending on the date of preparation in businesses dominated by seasonality, such as they often are in agriculture.

The four financial statements serve as the foundation for the basis of financial performance analysis. These historical documents assist managers in evaluating historical financial performance (trend analysis and benchmarking) and improving future financial performance.

Comprehensive analysis of the financial statements typically focuses on four key dimensions of financial performance: profitability, asset management, liquidity, and solvency. Each manager might tailor particular ratios to his or her firm, but generally aims to improve profitability and asset management while maintaining satisfactory levels of liquidity and solvency.

The most important financial metrics are return on equity (ROE) and return on assets (ROA). As the agribusiness competes for equity investments, it must generate sufficient returns to compensate investors for the level of risk incurred. Return on equity provides a benchmark ratio for which investors compare management's performance with other investment opportunities. Return on equity is impacted by the return on assets of the firm and the financial leverage used (see Section Capital structure), and is often analyzed using DuPont analysis of profitability linkage (**Figure 7**).

ROA measures the operating income generated for the investment in current and noncurrent assets. In the DuPont analysis, ROA is broken down into profit margin (or return on sales) and asset turnover. Profit margin measures the percent of revenue left to compensate financial capital. Asset turnover concerns the ability of management to generate sales (revenue) from the assets employed. Some firms pursue a low margin, high turnover strategy (often employed in retail firms). Other firms pursue high margin, low turnover strategies (often prevalent in manufacturing businesses). The ideal scenario would be to have a high margin, high turnover business.

The capital structure of the firm is concerned with the mix of debt and equity used to purchase the assets (see Section Capital structure). The financial leverage increases when more debt is used, and as a result there is more financial leverage applied to the return on assets of the business. Two broad financial concepts are of importance when considering the use of financial leverage: liquidity and solvency. The earnings leverage refers to the sharing of operating profit margin among lenders and equity holders.

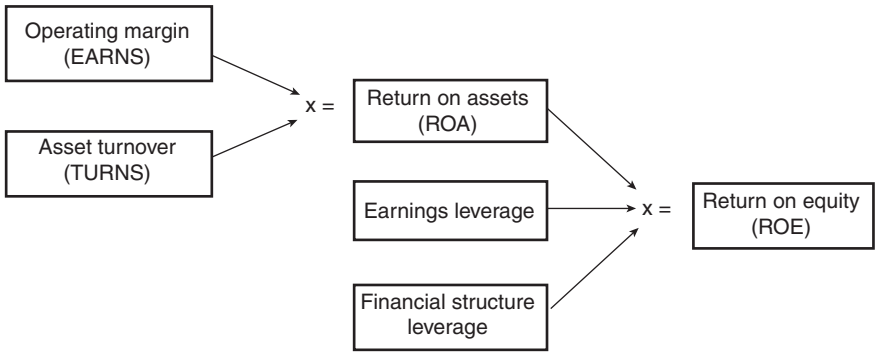

Figure 7 DuPont identity of return on equity.

Liquidity concerns the ability of the agribusiness to generate cash flows to service its debt obligations as they come due in the near term. Working capital, working capital turnover, the current ratio, and the quick ratios are all frequently employed to assess liquidity. Solvency concerns the ability of the agribusiness to meet its long-term debt obligations and is frequently measured by considering some form of the debt-to-asset ratio. Some research has considered the impacts of working capital and accrual changes on the profitability of agribusiness firms (e.g., Trejo-Pech *et al.*, 2009).

Investment analysis and capital budgeting

Agribusiness firms may seek opportunities to acquire assets to grow the business and create additional customer value. The process of evaluating these opportunities is known as investment analysis. Typically, the process involves assessing the likelihood of generating additional revenues into the future and comparing that to benchmarks for returns.

The investment analysis tool that most finance professionals would suggest using is net present value analysis (NPV) or discounted cash flow. The approach requires projection of cash inflows and outflows into the future, the determination of an appropriate discount rate, and typically some level of sensitivity analysis. The projection of cash flows typically begins with the initial outlay to acquire assets and tracks annual cash inflows and outflows related to the project. One must also make an assumption about the time frame of the project and determine a terminal (or salvage) value of the project. The lengths of projections vary, but typically are done for 5–10 or more years of cash flows.

The discount rate must be set to account for the time value of money and the required return needed to compensate the risk involved in the project. Many firms use their weighted average cost of capital (WACC) as the discount rate. This requires the project to generate sufficient returns to compensate financial capital at its current expected returns. Thus, if NPV is positive the firm should accept the project, otherwise reject the project.

Because the process is pro forma in nature, many analyses include testing the sensitivity of the results to important assumptions made in projecting the cash flows. Increased sophistication in spreadsheet programs has allowed sensitivity analysis to become rather detailed.

Firms can also choose to compute and report an internal rate of return for a project. This method uses the same techniques as the NPV analysis, but reports the discount rate that causes the NPV to be zero. This approach is appealing because it reports a rate of return that can be compared to rates of return in other investments or the hurdle rate set by company management. It has drawbacks in that some analyses may have more than one rate that causes NPV to be zero.

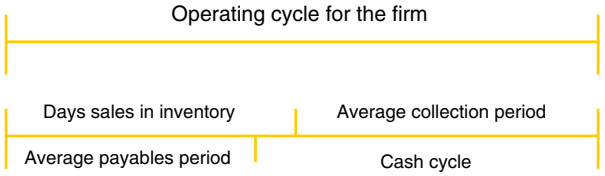

Figure 8 Operating and cash cycles for a firm.

Cash management

Short-run cash management requires agribusiness firms to have the cash necessary to settle accounts as they come due. The firm must have sufficient cash to pay suppliers, employees, management, and other expenses to continue daily operations. Typically, holding large amounts of cash to meet these needs is inefficient because cash held in checking accounts typically generates insufficient return for the firm to compensate the suppliers of cash. Investments in inventories, accounts receivable, and other current assets are additional important uses of cash that are part of operating cash flow. Firm will need to optimize investments in current assets and use of current liabilities to meet the operating needs of the firm. The management of these accounts is related to the cash conversion cycle (Figure 8).

Long-run cash management requires agribusiness firms to have sufficient cash or rapid access to sufficient cash to invest in long-term growth opportunities. Investments in fixed assets, typically termed investing cash flows, can require large amounts of additional capital to acquire the new, long-term assets.

Capital structure

The mix of debt and equity used to finance the purchase of assets is termed as firm's capital structure. The firm must balance the relatively lower cost of debt with the increased financial risk of borrowing. Firms should choose capital structure such that the WACC is minimized, which maximizes the value of the firm. An additional important consideration

in determining optimal capital structure is the tax shield benefits of using debt.

Agribusiness firms may raise financial capital in the form of debt from retail investment banks, the bond markets, and suppliers among others. The firms may also raise financial capital in the form of equity from private investors, the public equity markets, and retained earnings.

Financial risk increases as the debt-to-asset ratio increases. The increased borrowing demands greater cash flows from the business to service the debt. The increasing likelihood of the business being unable to meet the financing demands adds to the financial risk. If the business is unable to meet the demands, the borrowers will move to minimize the losses associated with a bankruptcy, i.e., dissolution of the business.

Operations

The operational activities of the firm are the set of actions taken to transform strategy and plans into deliverable products and services to generate financial and performance results (e.g., customer satisfaction). Operations activities include the full spectrum of work done in a business – running the manufacturing plant, shipping or transporting the product to the customer, sourcing the raw materials to produce the product or service, organizing and implementing the product/service sales activity, etc. Efficient and effective operations require an understanding and assessment of, for example, costs and cost components, product and work force flow scheduling and logistics, inventory management, sales and customer relationship management, selecting and managing the workforce, and capital access and financial management.

Economies of scope and scale

Firms often benefit from being large in terms of their assets and revenues. This happens because short-run fixed costs can be spread out over greater units sold, thus reducing overall average cost per unit. Firms of substantial size may gain cost advantages relative to smaller peers, particularly in industries with large fixed costs. Production of agricultural grain commodities exhibits this feature as land and equipment represent substantial costs. The same can be said for many agribusiness firms, particularly those involved in manufacturing and research and development activities.

Economies of scale refer to the cost advantages accrued to spreading the fixed costs of producing and marketing a singular product. Economies of scope concerns the ability of spreading shared fixed costs over the production and marketing of two or more products. Because many agribusiness sectors have large fixed costs, one often notes that the market has characteristics of a natural monopoly. Rapid consolidation in many sectors has left some with just a few firms operating in an oligopoly. Even in agriculture, the size of farms has grown as the number of farms has declined and acreage farmed has been held steady for about a century (Figure 9).

Logistics

Given the highly perishable nature of many agricultural products, regional production of some widely distributed products and the biological processes that govern agricultural production, excellent logistical management is very important for most agribusiness sectors. Moving products through time and space so that they reach the end consumer is the essence of logistics. Optimizing logistics focuses on reducing waste (shrinkage), minimizing transportation costs, and ensuring timely delivery.

Given that many agricultural products are very perishable, such as raw milk, many sectors are dominated by time specificity. Products must reach the end consumer when they are most desirable and useful, within a relatively limited period of time. Delays can cause enormous losses to the product.

Many agricultural sectors are dominated by complex distribution systems, which further complicate logistics. This interdependent network can delay important customer feedback along the supply chain. For example, many manufacturing sectors, such as farm equipment manufacturers, rely on others to distribute their products to the end users. Farm

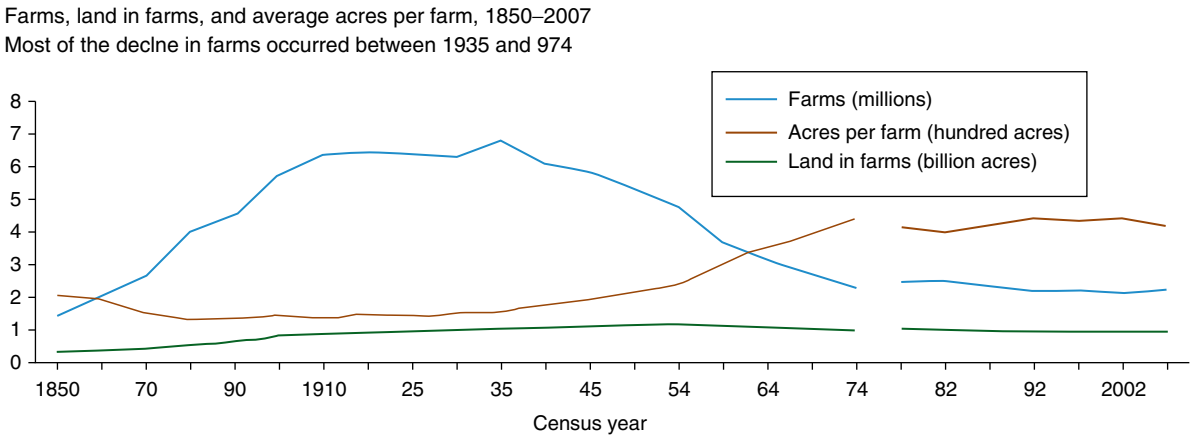

Figure 9 Farms, land in farms, and average acres per the US farm, 1850–2007. The break in the lines after 1974 reflects the introduction of an adjustment to estimates of the farm count and land in farms. Beginning in 1978, the data are adjusted to compensate for undercoverage by the Census of Agriculture. For more information, see Allen (2004). Reproduced with permission from Hoppe, R.A., Banker, D.E., 2010. Structure and Finances of U.S. Farms: Family Farm Report, 2010 Edition, EIB-66, July. U.S. Department of Agriculture, Economic Research Service, compiled from Census of Agriculture data.

equipment retail has been dominated by independent, equipment dealerships that have regional operating territories. To address the lack of communication between end user and manufacturer, increasingly sophisticated technology is being used on tractors to assess performance in the field. Specifically, engine sensors on farm equipment can transmit data for use by the producer, equipment dealership, and equipment manufacturer. This stronger integration of information across the value chain has the potential to greatly enhance the ability of the manufacturer to address user concerns as and when they arise.

Inventory management

Inventory management can play a large role in the success of agribusinesses. Production along the entire chain, particularly in the grain sectors, is dominated by the weather. As a result seasonality has a large impact on inventory management. Agribusiness firms growing seed for future crops must predict several years in advance to have the correct hybrids on hand for agricultural producers.

Inventory management should minimize total inventory costs by considering both carrying costs and opportunity costs. The carrying costs of inventory include the cost of storage facilities and equipment, the interest cost of inventory investment, and shrinkage of inventory. The opportunity costs of inventory are largely composed of missed sales due to insufficient inventory on hand to meet customer demands.

Inventory management can be complicated by the distribution channel. Given that each stage of the supply chain will hold inventories, communication along the chain will be critical in managing inventories of the sector.

Statistical process control and process mapping

Many agribusiness firms use statistical process control to assist with managing quality of products and services (Deming, 1982). Examples of process control include Total Quality Management and Six Sigma initiatives in these firms. The objective is to minimize waste in the production and processing of goods by ensuring that outputs meet certain specifications. One of the distinctive challenges faced by agribusinesses is the uncertainty surrounding the biological processes of production. This makes statistical process control both more challenging and more critical in the success of the value chain. In producing row crops, substantial data is collected and analyzed to help ensure large yields. For example, producers obtain information regarding nutrient health for soil samples. Pests and weeds are closely monitored and addressed as necessary.

Process mapping can also help to ensure the safety and quality of food as it moves through the value chain to the end consumer. In the food processing industries statistical quality control helps to reduce the incidence of foodborne pathogens. For example, food processors use Hazard Analysis and Critical Control Points (HACCP), International Organization for Standardization (ISO) certifications, and Clean in Place (CIP) processes to ensure food safety. The Food and Drug Administration and the US Department of Agriculture (USDA) work together to enforce HACCP systems in the meat and juice systems, whereas many other food industries voluntarily use the systems. The systems require firms to identify, set limits for, and monitor points in the production process at which control can be applied.

Human Capital Management

Human capabilities are essential for agribusinesses to transform assets and raw inputs into products and services that create value for consumers. Successful agribusiness firms have grown beyond the sole proprietorship with just one or two employees to become large, complex organizations that require communication and coordination to execute the firm's operational, financial, marketing, and research and development strategies. Managers throughout the organization need leadership skills to motivate and retain valuable employees. Firms often create a division of human resources to assist with identifying needed competencies and responsibilities of employees and employee competency development.

Organizational structure

As a firm moves beyond an entrepreneurial owner–operator size to a larger, more complex organization, frequently a corporate organizational structure emerges. The organizational structure varies by firm needs, but typically there is a hierarchy of responsibility and authority. At the top of the organizational structure is the President/Chief Executive Officer of the firm, which is hired by a board of directors to lead all functions of the business. Many firms then organize the structure around functional areas. They do so by having a senior manager (often with the title, vice-president) in charge of each functional area, who would report to the CEO. Many of these vice-presidents would have titles such as chief marketing officer, chief financial officer, and chief operating officer, among others. Additional members of the senior leadership team would be added as specific to the firm, such as a vice-president for human resources, vice-president for research and development, or a chief information officer. Firms might also have each of these roles for significant geographical areas or other market segments. One potential drawback to this particular structure is that the functional areas become silos that do not collaborate well with each other.

For the largest organizations the structure might become very complex. Each vice-president might have additional mid-level managers reporting to them that would be responsible for specific divisions within the functional role. These mid-level managers are termed middle management and can serve as a pool of candidates for senior leadership. Additional layers of management may be added between senior management and 'frontline' employees (i.e., factory line workers, sales and service representatives, etc.). The number of layers between the president and frontline employees is an indication of whether the firm has a vertical or flat reporting structure. Vertical structures are very hierarchical with clearly delineated reporting and authority relationships. Flatter structures tend to empower lower-level employees to a greater degree, which might negatively impact firm performance if the employees make poor choices.

Skills and competencies

Employees must come equipped with the requisite skills and competencies needed to maximize the efficiency and

effectiveness of physical assets used by the firm. Employees must be able to execute the implementation plan as it relates to the agribusiness's strategy. To do so, the agribusiness firm will attempt to share knowledge across employees and generations of employees. This can be a challenge though, as some knowledge is explicit whereas other knowledge is tacit. Explicit knowledge can easily be communicated from one person to another by writing it down. Explicit knowledge is often shared in user manuals and company onboarding programs.

Tacit knowledge was first identified by Michael Polanyi. In *Personal Knowledge*, Polanyi (1962) suggests that skills such as riding a bike and hitting a nail with a hammer are difficult to communicate in written form. Rather, the learner must acquire this knowledge by performing the action. Activities in the agribusiness firm that require tacit knowledge can be acquired through training programs that allow the learner to practice the skill in a low risk setting. Strong need exists for experiential learning in agribusiness given the tacit nature of much knowledge in agriculture.

Leadership

As employees move from a frontline role up the organizational structure, they may become managers and acquire direct reports. Direct reports are employees for whose actions the manager is responsible. Becoming a manager requires employees to develop a set of skills that will allow them to motivate their direct reports to maximize productivity for the firm.

Empirical studies by Lombardo and Eichinger at Korn/Ferry International have led to the Lominger Leadership Architect. This leadership development program identifies 67 competencies that are part of eight factors and 21 clusters (**Figure 10**). The eight factors are strategic skills, operating skills, courage, energy and drive, organizational positioning skills, personal and interpersonal skills, trouble with people, and trouble with results. The clusters help to identify skills that are closely related. Many of the competencies identified in the Lominger Leadership Architect are closely related to the development of the managers and executive leaders of food and agribusiness firms.

Currently, little empirical research has been done in the food and agribusiness industries to identify the application of these principles. The opportunities are abound as there has been documented need for additional human capacity to manage and lead the food and agribusiness sectors. Some data indicate, however, that an agribusiness talent gap exists and that the demand for professionals in the sector exceeds the amount of graduates from colleges of agriculture in the United States (USDA National Institute of Food and Agriculture). The USDA issued a report indicating that between 2010 and 2015 an estimated 54 400 jobs would be created annually in agricultural, food, and renewable natural resources. Only approximatey 29 300 students, however, are expected to earn degrees in traditional agriculture and life science-related fields during that same time span.

Human capital development

Firms often invest in the most recent technology for their physical capital. To gain the maximum benefit of this technology, the human capital employed by the firm must be able to implement and exploit this technology. Thus, large firms invest in educational programs for their employees that equip them with additional skills and competencies they may not have had when joining the firm. The ongoing educational, development, and training programs serve to strengthen the organization and its strategic mission.

As agribusiness firms move beyond training for frontline employees, they may begin to invest in educating employees to analyze and address complex problems. Very large agribusiness firms have learning and development departments that create and execute such programs. Some agribusinesses may turn to executive education programs offered by university and consulting firms. For example, the Center for Food and Agricultural Business at Purdue University partners with agribusiness firms to design, develop, and deliver such programs.

In addition to firm investments in human capital, individuals may choose to invest in their own education. One frequently acquired credential is the master of business administration or, specific to agribusiness professionals, a master of agribusiness. For example, Kansas State University offers a Master of Agribusiness degree focused on management education for agribusiness professionals. Other universities offer courses on agribusiness in their more general MBA programs (**Table 3**).

Entrepreneurship, Innovation, and Research and Development

Innovation is essential for meeting changing consumption patterns and improving efficiency along the food chain. Innovation is needed among input suppliers, plant and animal agricultural producers, food distributors, and food retailers to satisfy consumers. Efficiency will come from diffusion and knowledge transfer. When properly produced and used, agricultural inputs help farmers improve yields of high quality products that allow consumers safer, more wholesome, and cheaper food. When considering animal and plant production, agribusinesses need to work in tandem with producers to increase land productivity, shorten plant production cycles, increase efficiency in land operation and management, search for lower environmental impact technologies, have more efficient and conservative soil operations, have localized and adapted solutions and use renewable energy sources for fueling the high energy demanding agricultural activities. Feeling the pressure for more environmental friendly, healthier, and distinguished products, the agro-industry has invested on ecological packing, products with different or enhanced flavor, products that satisfy appetite and work as medicines or cosmetics. The food retail innovation brings us to supermarkets promoting new buying experiences, such as tasting areas, new ways to offer the products, offering complete solutions, increasing benefits for consumers, supermarkets becoming a place of knowledge transfer, where the consumers learn about the products they eat, becoming a place where the industry communicates with its final consumers. Supermarkets are trying to regain some market share that they have been losing to foodservice, such as restaurants, by adding more of the home meal replacement strategies.

Entrepreneurship and entrepreneurs

Entrepreneurship is the capacity and capability to identify new business opportunities and to successfully bring that opportunity to market and generate superior (or at least acceptable) financial performance. Entrepreneurs are commonly perceived as risk-takers – they embrace new ideas and are

Table 3 Educational programs in agribusiness management

willing to encounter financial losses or other exposures to introduce them to the market. In reality entrepreneurs are uniquely skilled at identifying, managing, and mitigating the risks of their new ventures. McGrath and MacMillan (2000) suggest that entrepreneurs have five fundamental characteristics:

1. Passionately seek new opportunities
2. Pursue opportunities with focused discipline
3. Pursue only the very best options – prioritization is critical to success
4. Focus on execution – the entrepreneur doesn't just stop with invention or discovery
5. Engage broad participation in their venture – an inventor may work alone with few collaborators, but a successful entrepreneur is skilled at engaging a large set of participants to bring the new idea to market

McGrath and Macmillan (**Figure 11**) provide more specificity concerning the skills and capabilities critical to successful entrepreneurship.

Innovation and research

Innovation is critical to the long-term success of a firm as well as the economic health of an industry and the overall economy (Gertner, 2008). Brown and Teisberg (2003; p. 1) state that "Innovation is the lifeblood of successful businesses. […] [It] has become every firm's imperative as the pace of change accelerates." Indeed, innovation is a strategy to develop and maintain a sustainable competitive advantage.

Innovation can be a product, a service, a process, a new business model, or a management system that solves a problem and has impact. The food and agribusiness sector is no stranger to innovation. Over the past 150 years, there have been several waves of innovation related to machinery, chemistry, seed, information management, food, restaurants, and services.

In addition, innovation is and will remain essential in the food and agribusiness sector to respond to the critical concerns of society such as new consumer demands, climate change and global warming, food/energy scarcity and security, environmental challenges, and resource use/sustainability. In a recent study by McKinsey on innovation and resource productivity to meet the world's future energy, materials, food, and water needs, four of the top ten opportunities are in the agricultural sector, presenting excellent opportunities for profitability new business ventures: increasing yields on large-scale farms, reducing food waste, increasing yields on smallholder farms, and reducing land degradation.

A key issue in agribusiness R&D and innovation is the length and complexity of the value chain and the challenge is in bringing innovations from the input end of the chain created by the physical and biological sciences of engineering, genetics, nutrition, biotechnology, and nanotechnology to successful market acceptance and adoption at the retail and restaurant (foodservice) consumer end of the value chain. This issue is compounded by the dramatic changes recently in the end uses (bio-fuels, industrial products, etc.) of agricultural raw materials and the development of new value chains in the bio-economy.

The degree of innovativeness – 'new to the world' products compared to incremental 'repositioning' of products – also has a significant impact on structural entry barriers. Disruptive/radical discontinuous innovation by a new entrant can facilitate entry by:

1. Use of new/different resources/inputs, thus challenging the incumbent's control of essential resources;
2. Dramatically lowering the cost of production/distribution; and
3. Introducing superior performing or lower cost products that offset the switching costs of current customers and attract noncustomers.

The long-term implications are for significant challenges to incumbent agricultural production technology firms, as well as product processing firms, as renewable biological-based raw materials become the feedstock not just for food and fiber end-users (the old customers), but for the health/pharmaceutical and industrial products end-users (the new customers) as well.

Managing research and development

Selection of R&D projects: after identifying innovative ideas, a key challenge is to select which ideas will be pursued as part of the R&D portfolio. Most organizations find that they have several good ideas but lack the framework required to select and convert the best ideas into new revenue. With regard to selection criteria, Roucan-Kane (2010) found that food and agribusiness executives prefer (in decreasing order of importance) projects with low risk of technical/regulatory failure, low relative market risk, short-term to market, in-house capability, and high costs already incurred. This work suggests that strategies to manage the risk of technical/regulatory failure and market acceptance merit serious consideration (**Figure 12**).

One way to manage the technical/regulatory and market risk is to select a portfolio of innovation projects with varying degrees of risk as suggested by McGrath and MacMillan (2000). Boehlje *et al.* (2011) illustrate the use of the McGrath

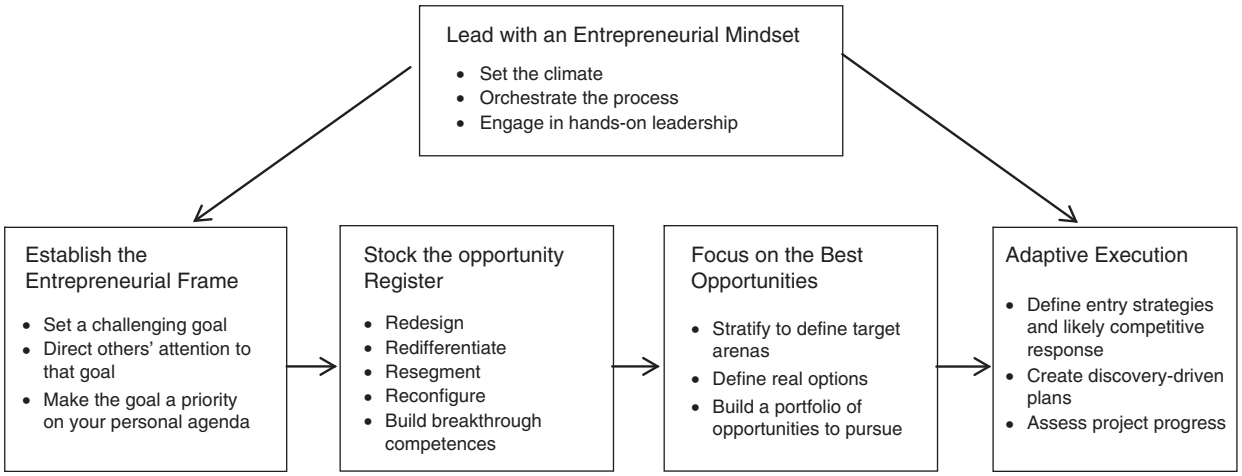

Figure 11 Essentials of entrepreneurial strategy.

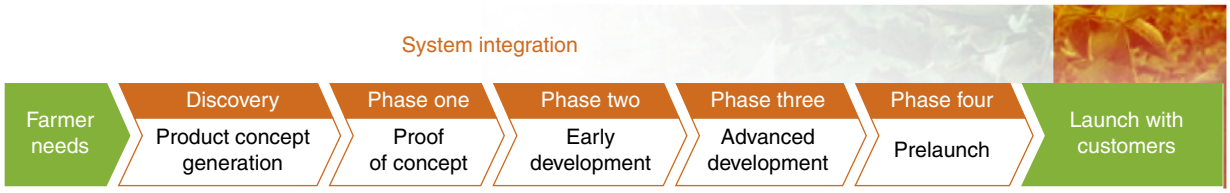

Figure 12 Monsanto's research and development pipeline.

and MacMillan 'portfolio of options' framework to Deere and Company's innovation projects (Figure 13). The framework suggests a diversified portfolio of positioning, stepping stone, and scouting options along with platform and enhancement launches to manage market and technical uncertainties.

Roucan-Kane studied the portfolio of innovation projects for food and agribusiness companies using the same criteria as described earlier. Her survey results indicated that companies tend to diversify their innovation projects in terms of time to market and cost already incurred. They favor projects that are done in-house, and that are not characterized by significant risk of technical/regulatory failure or high relative market risk.

Managing the R&D pipeline: the selection of R&D projects should be regularly reviewed as uncertainty is resolved and new projects enter the pipeline. Cooper's stage-gate process (Cooper, 2001) proposes a structure to continuously analyze the portfolio of innovations and increase the likelihood of success in an uncertain world. His process features five innovation stages: scoping, building a business case, developing, testing and validating, and launching. Each stage (and sometimes within a stage) ends with a gate where the resource allocation and the prioritization of projects is reviewed and changed if needed.

Deere and Company calls its stage gate processes the Enterprise Product Development Process (EPDP) and the Accelerated Innovation Process (AIP). EPDP focuses on incremental innovations, ensuring that these innovations reach the quality standards Deere has set before the product is launched. AIP is targeted toward radical innovations with the use of selection methods such as strategic buckets, structured assessment, and economic models.

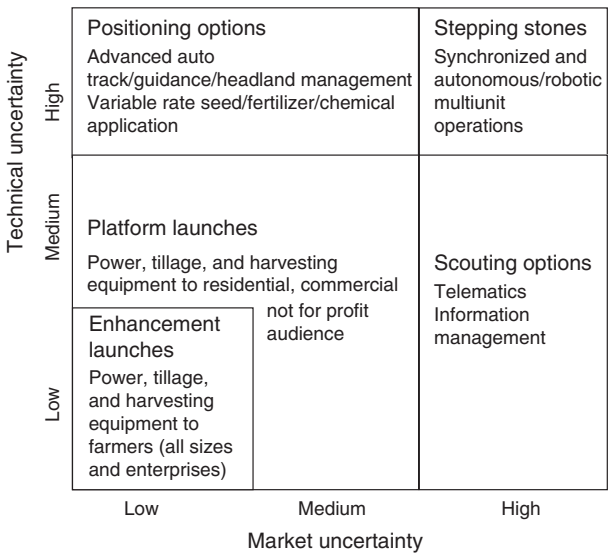

Figure 13 Deere portfolio of innovations. Adapted from Boehlje, M.D., Roucan-Kane, M., Broring, S., 2011. Future agribusiness challenges: Strategic uncertainty, innovation and structural change. International Food and Agribusiness Management Review 14 (5), 53–82.

Conclusions

The purpose of this article is to discuss contemporary topics in food and agribusiness with a focus on definition of agribusiness, description of the global agribusiness environment,

and a discussion on the roles in managing an agribusiness firm. Managers in the agribusiness sector need to be aware of the interrelated subsectors that work together to provide goods and services to global consumers. To be successful in the sector, managers must be able to competently integrate skills and capabilities in the areas of strategy, marketing, finance, operations, human capital, entrepreneurship, and innovation.

Glossary

Equity subscription and redemption Procedures used to determine each member–patron's required annual capital contributions to, and capital withdrawal entitlements from, the cooperative.

Investor-owned firm A firm in which ownership and control are proportionate to equity capital invested, rather than according to use of the firm's services.

Liquidity The ease or cost with which an investor's capital can be converted into cash.

New generation cooperative A marketing cooperative structure stressing closed membership, transferrable and appreciable stock shares, proportionality between equity contribution and patronage, and well-defined marketing contracts requiring as well as guaranteeing member raw product deliveries on stated quantity and quality terms.

Patronage The value of a member's raw product supplied to – or inputs purchased from – a cooperative, which is calculated at estimates of the current market prices of the products supplied or inputs purchased.

Pool The combined net revenue from the whole or a subset of the cooperative's operations, which is allocable to the members who contributed to that subset of operations. Normally, a marketing cooperative's 'pool' refers to revenue less processing cost only, that is, the value of member-delivered raw product is not included in the cost accounting.

Revolving fund The facility in a traditional cooperative for annually retaining equity capital in proportion to a member's patronage that year, holding it without interest, and then redeeming it in cash after a prearranged period or – more typically – when the board chooses to redeem it.

Tax-exempt cooperative A cooperative entitled to exclude from taxable dividends any dividend paid on stock and any nonpatronage income allocated to member and nonmember patrons. Such cooperatives must treat nonmembers the same as members in all respects, including dividend distribution.

Traditional cooperative A marketing, supply, or service cooperative structure stressing open membership, nontransferrable and nonappreciable equity shares, capital subscribed according to patronage but redeemed at the board's discretion, and – in marketing firms – delivery contracts emphasizing member rights rather than obligations.

Unallocated revenue Revenues held on the cooperative's books in unallocated form, that is, not allocated to the account of any particular member.

Introduction

A cooperative is a business owned by the users of its services. In particular, it is a firm whose net revenues are paid to the firm's patrons and on the basis of that patronage. The principal alternative to a cooperative is an investor-owned firm – one owned by those who have invested capital in it, but who do not necessarily patronize its services. An investor-owned firm's net revenues are paid to its equity holders in proportion to the capital they invest rather than, as in a cooperative, according to their patronage. Farmer cooperatives supply farmers with their production inputs, process and market their products, and sometimes provide other services such as price bargaining and trucking. Hence, understanding cooperative organization is essential to understanding the business of agriculture.

Concept of a Cooperative

Cooperative Principles

Cooperative organization of economic activity has a long history, including the collective work efforts of early agricultural societies. The first group of individuals to organize as a modern cooperative was the Society of Equitable Pioneers (1844), a firm established in Rochdale, England to supply its 28 members with weaving materials. Its purpose was to provide inputs to its members at cost and to be controlled on a one-member-one-vote basis. Services to members were to be provided at cost.

In modern cooperatives, democratic member control is still regarded as an essential principle, although voting rights in some firms are distributed according to the member's patronage rather than on a one-person-one-vote basis. The principle of at-cost service also remains. This second principle essentially means that the bulk of the cooperative's net income is distributed (in cash or stock) as a return to patronage, in turn requiring strict limits on the proportion of income distributed as a return to equity. Member–patron control, service at cost, and limited payments to equity capital are, then, the basic elements of a cooperative firm.

Operation at Cost

A brief example will show why paying net margins to members according to their patronage (i.e., to use of the firm's services) is equivalent to providing services to members at cost. Table 1 gives the example of a farm supply cooperative whose business is to supply farmer members with inputs such as fertilizer. The cooperative buys 10 000 units of fertilizer from the manufacturer at a wholesale price of US$0.30 per unit. The cooperative's handling cost is US$0.10 per unit, giving a total raw product and handling cost of US$4000. For simplicity, suppose there are only two members. Member A receives

 doi:10.1016/B978-0-444-52512-3.00125-X

Table 1 Net revenue distribution in a hypothetical supply cooperative

Cooperative costs					
Wholesale cost of fertilizers		*Operating costs*		*Total cost*	
Per unit	Total	Per unit	Total	Per unit	Total
$0.30	$3000.00	$0.10	$1000.00	$0.40	$4000.00
Shipments to members					
Member A			*Member B*		
Units	Retail price	Total patronage	Units	Retail price	Patronage
3000	$0.45	$1350.00	7000	$0.45	$3150.00
Net return distribution					
Member A			*Member B*		
Patronage share	Patronage refund	Unit price (cost to member)	Patronage share	Patronage refund	Unit price (cost to member)
3000/10 000 = 30%	$150.00	$0.40	7000/10 000 = 70%	$350.00	$0.40

shipment of 3000 units and member B receives 7000 units from the cooperative. It is assumed that the retail price charged by the cooperative's fertilizer supply competitors is US$0.45 per unit and the cooperative charges this same price to its members on delivery. Member A's total cooperative patronage is 3000 × US$0.45 = US$1350; similarly, member B's patronage is US$3150. Hence, the cooperative's total business volume or revenue is 10 000 × US$0.45 = US$4500.

The cooperative earns a total net return of US$4500 − US $4000 = US$500. The reason for this positive profit is that wholesale price plus per-unit operating cost is less than retail price. To satisfy the at-cost principle, net returns must be distributed to members according to patronage. Inasmuch as member A accounts for 30% of the patronage, he/she is entitled to 30% of net returns or a patronage dividend of US$150 (US$0.05 per unit). Member B accounts for 70% of patronage and so is entitled to 70% of net returns, giving him/her a patronage dividend of US$350 (US$0.05 per unit). Provided the fertilizer is a homogeneous good, the per-unit patronage dividend will be the same for both members as well. Net cost per unit to each member is the retail price originally paid (US $0.45) less the per-unit patronage dividend (US$0.05). That is, members buy fertilizer at cost: a US$0.30 wholesale price plus US$0.10 operating cost. In this particular example, members buy fertilizer US$0.05 per unit cheaper than they would from the cooperative's competitor.

Contrast with Investor-Owned Firms

Although a cooperative distributes net returns or losses primarily to users of the firm's services, an investor-owned firm (IOF) distributes net returns to shareholders, that is, to owners of the firm's capital (Hansmann, 1996). Suppose the fertilizer distribution firm in Table 1 is an IOF rather than a cooperative. Sales quantity, costs, revenues, and total net returns (US $500) are assumed to be the same as in Table 1. If shareholder 1 owns 100 of the 150 shares outstanding, he/she claims two-thirds of the US$500 net return (US$333.33). If shareholder 2 owns the remaining 50 shares, he/she claims one-third of the US$500 net return (US$166.67). The contrast with a cooperative is the clearest if it is imagined that shareholder 1 is the same person as farmer A in Table 1 and shareholder 2 is the same person as farmer B. Farmer A pays US$1350 retail for his/her fertilizer and, as shareholder of the firm, receives US $333.33 in dividends. Farmer B pays US$3150 retail for his/her fertilizer and receives US$166.67 in dividends. Net price to farmer A is US$0.45 − (US$333.33/3000 units) = US$0.34. Net price to farmer B is US$0.45 − (US$166.67/7000 units) = US$0.43. The distribution of the fertilizer cost between the two farmers has shifted considerably from that prevailing in a cooperative.

Modern History and Types of Cooperatives

Modern History

Agricultural marketing cooperatives operated successfully in the United States as early as the 1810s. They included cheese makers, hog processors, and grain elevators. The National Grange, founded in 1867, organized thousands of local associations to purchase farm inputs and sell farm products collectively. Most of them, and successor locals organized by the Farmers' Alliance, had failed by the turn of the century, but the Farmers' Union, founded in 1902, continued the work of establishing county-level supply and marketing coops. The American Farm Bureau Federation also began fostering local cooperatives in the 1920s. Successors of the Farmers' Union and Farm Bureau coops include some of the major cooperative associations of today.

The worldwide cooperative movement received a significant boost through the expansion of the British Empire in the late 1800s. British officials encouraged formation of local cooperatives, linked to national cooperative unions. Most local coops acted as agents for the British-instituted agricultural marketing boards. Agricultural cooperative unions in many low- and medium-income nations remain dependent on

government support; however, such support is waning and they are beginning to stand on their own.

In the US, the Sherman Antitrust Act had in 1890 outlawed "every contract, combination... in restraint of trade." Cooperatives are collective arrangements between farm firms and hence were widely regarded as examples of such illegal combinations. The Clayton Antirust Act (1914) thus specifically authorized "... agricultural or horticultural organizations... not having capital stock..." The more numerous capital stock-based associations then were legalized by the Capper–Volstead Act (1922), widely regarded as the 'magna carta' of farmer cooperatives. Coops legalized by Capper–Volstead must conduct a minority of their business with nonmembers and either be organized on a one-person-one-vote basis or restrict stock dividends to 8% or less. Capper–Volstead assured that a cooperative's mere existence would be insufficient evidence of illegally collusive behavior. Furthermore, Section 2 of the Act allows coops to affect prices as long as they do not do so 'unduly.' Most cooperatives are chartered in a particular state and therefore are subject to state-level incorporation regulations as well.

A Central and 12 regional Banks for Cooperatives were established by the Farm Credit Act of 1933. In 1989, the 11 of the 13 banks merged to form CoBank; the remaining two – in Massachusetts and Minnesota – remained independent. Equity in these banks is held by the cooperatives that borrow from them, and interest rates are determined by the cost of CoBank's capital plus operating costs. In addition to its loans to direct retail borrowers such as coops, the bank provides wholesale loans to affiliated lending associations in the Farm Credit System.

In 2001, when data last became available, approximately 28% of the value of farm products in the US appeared to have been sold through processing/marketing cooperatives and approximately 26% of the value of farm supplies purchased through supply cooperatives. These overall percentages seem to have changed little since the early 1980s. Breakdowns of cooperative market shares in 1996 and 2001, based on rather spotty information, are shown by type of farm product and farm input in **Table 2**. Marketing cooperatives' shares of farm sales range from 0% to 21% in Britain, whereas they range from 20% to 83% in Germany. In recent decades, some US cooperatives have converted into an investor-owned form or have adopted forms combining investor-owned firm with cooperative features (US Department of Agriculture, Rural Development Division, 2010).

Types of Function

Agricultural cooperatives in the US consist of supply, marketing, service, and bargaining cooperatives. Supply coops, illustrated in **Table 1**, provide members with farm inputs such as machinery, fertilizers, pesticides, feed, and fuel. Marketing coops assemble, process or handle, and sell members' farm products. Service coops provide trucking, storage, and other services in which the member retains title to his farm commodity. An important form of service cooperative is the bargaining coop, which acts as farmer–members' agents in negotiating prices and other trade terms with farm product buyers. Some cooperatives provide supply as well as marketing services. Business volume in both supply and marketing cooperatives appears, in constant dollar terms, to have remained approximately flat from 1980 to 2005, and then risen after 2005. Marketing cooperative volume usually has been well over twice that of supply cooperative volume, although since 2005 it has declined to just less than twice (US Department of Agriculture, Rural Development Division, 2010).

Cooperatives are encountered frequently outside agriculture. Examples in the financial sector are mutual insurance companies, mutual savings banks, credit unions, group health plans, stock exchanges, and boards of trade. In the housing sector, they include community associations and condominiums and, in the consumer sector, utility cooperatives, food coops, cooperative nursery schools, and buying clubs of various kinds. Such organizations are true cooperatives if they are run democratically and refund net returns to members in proportion to patronage. Mutual insurance companies, for example, distribute profits in the form of dividends on customers' policies.

Types of Centralization

An agricultural cooperative in the US is considered a local, federated, centralized, or mixed one. Local cooperatives serve farmers in a small area such as one or two counties. A federated cooperative is one whose members are local cooperatives. A federated supply coop might engage in phosphate mining

Table 2 Cooperative share of agricultural business, 1996 and 2001

Products marketed	*Percentage of cash receipts*		*Farm input*	*Percentage of farm production expenditures*	
	1996	*2001*		*1996*	*2001*
Milk and milk products	83	83	Fertilizer	44	45
Cotton	32	43	Petroleum	44	46
Grains and oilseeds[a]	45	38	Crop protectants	32	34
Fruits and vegetables	19	19	Feed	21	15
Livestock	13	13	Seed	10	13
Total[a]	31	28	Total[b]	28	26

and fertilizer mixing, transferring the mixed fertilizer to its member locals in order to be distributed to the locals' farmer–members. A federated's net returns are distributed to member–locals in proportion to the local's patronage, and a local's receipts are, in turn, distributed to the local's farmer–members in proportion to members' patronage in the local. Federated coops are sometimes referred to as secondary cooperatives or, in Britain and many other countries, as cooperative unions. Centralized cooperatives operate like locals, that is, admit only individuals as members. The difference between a local and a centralized firm is only in size, the centralized cooperative usually being similar in size to a federated cooperative. Mixed coops are those that admit both individuals and local cooperatives as members.

Like other agricultural firms, US cooperatives are – by merger, acquisition, or dissolution – becoming fewer and larger. The number of marketing cooperatives in the United States fell from approximately 1800 in 2001 to 1218 in 2010. The number of supply cooperatives fell from approximately 1300 to 975. An additional 117 cooperatives were providing services such as trucking, storage, and crop drying in 2010. During that same 2001–2010 period, the number of individual cooperative memberships fell from approximately 5.7 million to approximately 2.2 million. The number of farm memberships, however, remained almost constant. Of the 2310 cooperatives operating in 2010, 2252 were organized on a local or centralized basis, 38 were federated, and 20 were mixed (US Department of Agriculture, Rural Development Division, 2010).

Economic Theory of Cooperatives

The economic theory of cooperatives is a set of related statements about how members, directors, and employees would behave – and what they would achieve – given assumptions about their objectives and resources. Some theorists have considered the cooperative as a single decision-making entity. Others have considered it instead as a loose collection of individual agents, each seeking to promote his/her own special interest. These two schools of thought will be considered in turn, focusing on a single-product marketing cooperative as an example. Application to a supply cooperative is straightforward.

Single Decision Entity

The board of directors may pursue a number of alternative objectives including: (1) maximizing the price paid to members per unit of product delivered (including initial price and per-unit patronage dividend); (2) maximizing members' total – that is farm plus processing – income; and (3) permitting free entry to the cooperative. These competing objectives are best characterized by defining the firm's net margin (NM) function as

$$\mathrm{NM} = Pf(X,R) - WX$$

where P is the price the cooperative receives from selling the good in the final product market (after processing and handling); $f(X,R)$ is the quantity of final good sold, which, in turn, is a function of the resources X used in processing/handling and of the quantity R of the raw good received from members; and WX (the product of vector W of prices and vector X of the resources purchased at those prices) is the cost of resources used in processing and handling. Net margin, NM, excludes the value or cost of member raw product. The cooperative's service-at-cost principle requires that NM be entirely paid to members or patrons, although the practice of holding unallocated revenue violates this principle to some degree.

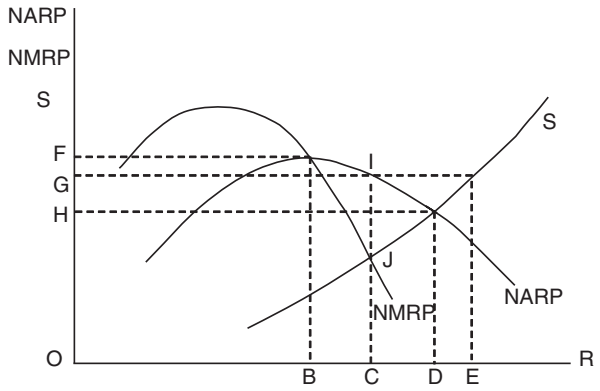

Figure 1 Alternative output rates in a marketing cooperative.

Assuming that the cooperative utilizes its resources X to maximize net margin at any raw product level R, maximized net margin (NM*) can be divided by R to obtain the net average revenue product function (NARP):

$$\mathrm{NARP} = \mathrm{NM}^* R^{-1}$$

Similarly, (NM*) can be differentiated with respect to R in order to obtain the net marginal revenue product function (NMRP):

$$\mathrm{NM}RP = \partial \mathrm{NM}^* / \partial R$$

NARP and NMRP are depicted in Figure 1. As raw product volume rises, NARP first rises as well. The reason is that specialization and learning-by-doing allow per-unit processing costs to fall as volume is boosted. Thereafter, NARP declines as diminishing returns to fixed resources set in or as output price P begins to fall. Where NARP reaches its highest point, NARP and NMRP always equal one another (Royer and Smith, 2007).

Also included in Figure 1 is the cooperative members' supply curve S. This curve represents the horizontal summation of all members' marginal costs of farm-producing the commodity in question. In other words, S represents, at a given raw product production level R, the cost of producing one more unit of the commodity.

Inasmuch as *NARP* is the full per-unit price the cooperative pays each member for product delivered (including initial price and per-unit patronage dividend), operating at raw-product volume B in Figure 1 would achieve objective (1), namely creating (at F) the greatest value per unit of raw product. Objective (2) would be achieved by operating at raw-product volume C instead, where member supply function S intersects the *NMRP* function. This is the full-income-maximizing point

because it equates the marginal cost of farm production with the marginal net revenue from its sale on the final-product market. Finally, objective (3) is achieved by operating at raw-product volume D because, at any lower volume, the full raw-product price paid by the cooperative (height of the NARP function) exceeds the minimum price a potential member would accept (height of supply function *S*) (Clark, 1952; Helmberger and Hoos, 1962; LeVay, 1983).

Solution (2) is socially optimal in the short run because it equates the marginal cost with the marginal benefit of member raw product. However, it is a complicated solution to enforce. If CJ is paid to members as their initial price, JI would be the per-unit patronage dividend. Full price would be CI. But this price would induce members to produce and deliver quantity OE rather than OC. A way must be found to limit supply to OC or to allocate the cooperative's net margin on a nonpatronage basis. In contrast, free-entry Solution (3) would reduce members' net incomes to zero in the long run. The reason is that free entry to the cooperative would shift raw-product supply curve *S* to the right until the cooperative payment per unit of raw product is reduced to the member's per-unit cost of production, as opposed to marginal cost of production represented by raw-product supply curve S (Sexton, 1986). Actual cooperative pricing practice varies widely (Sexton *et al.*, 1989; Soboh *et al.*, 2009; Yoo *et al.*, 2013).

Multiple Decision Entities

A distinction should be made between (1) whether members would initially agree to any given raw-product pricing policy and (2) whether that policy would remain feasible in the sense of providing an incentive for every member to remain in the cooperative once the policy is enforced. The former question, a collective choice one, can be addressed by first specifying the cooperative's voting process, then determining whether the price policy would be selected by majority vote, given the characteristics of the individual members. The latter question, one of membership stability, has been addressed through the use of 'cooperative games,' in which the analyst specifies the minimum incomes which various subgroups of the membership would earn if they formed their own cooperative or traded instead with an IOF. Cooperative games – which may be applied to many situations other than to cooperative business firms – are useful if members differ from one another in farm size, efficiency, or other factors.

Consider, for example, the case in which the cooperative's per-unit operating cost is substantially lower at the present volume than at the smaller volume that would result if some members quit. Under a number of reasonable assumptions about the cooperative's cost structure, it is easy to show that larger volume members could credibly threaten to quit unless they were granted concessionary pricing terms. Furthermore, it would often be in the interests of smaller members to grant such concessions to forestall the cooperative's breakup. In the absence of concessions (which would involve departing from the simple patronage-based dividend allocation shown in Tables 1 and 4), a breakup would occur unless the larger members were motivated by altruism or other extra-economic objectives. For this reason, it has been observed that solution (i), point B in Figure 1, may be the long-run equilibrium volume of a cooperative, because a subgroup of members can increase its incomes by breaking off to operate at this more efficient point.

Cooperative Management

Pricing and Pooling

The cooperative's elected board of directors establishes policy and oversees the activities and performance of hired management. Board members usually are chosen on a rotating basis at the annual meeting or by mail ballot. Issues about which the board must decide include types of offered services, pricing and pooling, financial structure, credit, and member and employee relations. The authors will consider pricing and pooling in the next two paragraphs. The context used is again that of a marketing cooperative.

A few marketing cooperatives credit a member with the full market value of raw product on its delivery to the coop for processing or handling. This market value is then debited, along with other costs, from the cooperative's revenue to determine the net margins that will be allocated back to the member on a patronage basis. Coops that operate this way may be termed 'buy/sell' coops. 'Pooling' cooperatives are those which do not credit members with the market value of their raw products on delivery and which, therefore, do not debit raw product value from the returns eventually allocated back to members on a patronage basis. In either event, part of the member's allocation usually is paid in cash, part in equity certificates. If raw products are homogeneous across members, the decision whether to credit a member on delivery with the market value of his/her product does not affect the sum of payments he/she will receive from the cooperative.

A complicating factor is that most cooperatives deal in heterogeneous products, either in the sense of various grades of the same commodity or of various commodities. Such grades and commodities can, for payment purposes, be grouped in any way the cooperative chooses. Let P_j be the per-unit valuation (often the raw-product market price) of the *j*th raw product, Q_j the quantity of *j* supplied by members, and R_j its per-unit resale revenue in the final product market less the cooperative's per-unit operating cost (including any member credits at delivery time). Assume the firm operates a number of separate pools and let J_k represent the subset of the firm's products included in the *k*th pool. The cooperative's per-unit payment to members for the *j*th raw product shipped to the *k*th pool is (Buccola, 1991):

$$\text{Unit payment} = \left[P_j\left(\sum_{J_k} P_j Q_j\right)^{-1}\right]\sum_{J_k} R_j Q_j$$

The member producer of product *j* participates in the net earnings of all products involved in the pool in which *j* belongs. Products often are pooled in this way to reduce member risk through diversification or to simplify accounting or because the raw products are commingled during processing. Raw-product valuations, P_j, are in many cases difficult

to establish and create significant conflict on the board of directors.

Equity Subscription and Redemption

As indicated above, part of a member's patronage refund (which may in a marketing cooperative include some or all of the 'market value' of the raw product) normally is paid in the form of a certificate, the corresponding cash withheld to provide the firm's equity capital base. Besides withheld patronage dividends, coops have two other ways to subscribe equity capital: outright purchase (often when a member joins) and reunit retains. The latter are used primarily in marketing firms and consist of a fixed capital obligation for each physical or value unit of commodity that a member delivers to the cooperative.

Equity subscribed by withheld patronage dividends, outright purchase, or per-unit retains can be accounted for in either stock or nonstock form. The principal nonstock device is the certificate of equity, variously known as a revolving-fund, patronage-refund, or revolving-capital certificate. The equity portion of the cooperative's balance sheet indicates each member's equity share of the firm as determined by the value of his/her equity certificates and book credits. In the conventional cooperative structure, most certificates and credits carry no vote, are nonnegotiable (cannot be traded), and bear no interest.

Approximately three-quarters of the US cooperatives are organized on a stock basis, that is, account for a part of a member's equity through stock certificates. Some issue a limited amount of preferred stock, which in most states is limited to a dividend rate of 8% or less. Common stock, found more frequently, usually does not pay dividends and is nonnegotiable. Except as specified in the cooperative's equity retirement plan (see next paragraph), it cannot be cashed in for more than its par value, which generally is quite low. Preferred and common stock typically account for the minority of the firm's equity capital. A portion of a coop's equity normally is also held in unallocated form – not allocated, that is, to the account of any particular member (Barton and Schmidt, 1988; US Department of Agriculture, Rural Development Division, 2011).

A member's allocated capital, whether in stock or nonstock form, can be revolved or redeemed (paid in cash) to the member in a number of ways. Table 3 lists the alternatives and the percentages of cooperatives employing them in supply and (as an example) in grain- and oilseed-marketing cooperatives. Most financial analysts favor one of the bottom three methods in Table 3. Age-of-Patron and Estate-Settlement methods allow the quickest growth in cooperative operations but, especially in view of their noninterest-bearing nature, create illiquidity by depriving members of their equity contributions for long periods. Rotation cycles in a coop's Revolving Fund plan tend to vary at the board's discretion, so member payouts are often rather unpredictable. Under reasonable parameter assumptions, the Percentage of Pool plans yield members the highest present value of redemption cash flow. Base Capital plans best ensure that a member's proportionate share of capital investment remain close to his patronage share of the firm's business. Until recently, however, they have been rarely used (see Section New Generation Cooperatives). In recent decades, cooperatives have tended to move away from the Estate Settlement method to Revolving Fund approaches (US Department of Agriculture, Rural Development Division, 2011).

A key objective of the cooperative's equity plan should be proportionality between capital investment and patronage because, in its absence, the owners of the cooperative are not exactly its users. The nature of the equity redemption scheme is, in fact, more important in a cooperative than in an IOF. In the latter, returns are obtained partly when dividends are paid on the stock and partly when it is sold. Because, in a cooperative, stock and nonstock certificates are almost always nonnegotiable, members usually depend on the Board's equity redemption policy for reclaiming their investment.

Taxation

The Revenue Act of 1913, which established income taxation in the US, exempted 'agricultural and horticultural associations' from income tax. The argument was that such associations allocate most of their net earnings to individual members and hence do not earn a profit as corporate entities.

Table 3 Cooperative equity redemption plans

Plan name	*Description*	*Percent of the US supply cooperatives using (2008)*[a]	*Percent of the US grain/oilseed-marketing cooperatives using (2008)*[a]
Age of patron	Redeem all capital when member reaches a specified age (e.g., 65 or 70)	38	30
Estate settlement	Redeem all capital at member's death	50	58
Revolving fund	Redeem all capital held at specified number of (e.g., 10) years	43	45
Percentage pool (% of all equities)	Annually redeem a constant specified percent of member's allocated equity	17	13
Base capital	Redeem or subscribe capital to maintain fixed proportion to member's recent average patronage	2	1

[a]Because cooperatives often simultaneously use more than one equity redemption method, percentages do not sum to 100.

Table 4 Taxation of a hypothetical supply cooperative

Recent value of sales	US$26 000 000.00
Operating cost	23 500 000.00
Net margin	2 500 000.00
Pretax unallocated revenue	250 000.00
Tax on unallocated revenue (@ 35%)	87 500.00
After-tax unallocated revenue	162 500.00
Allocatable member income	2 250 000.00
Total value of goods sold to members	26 000 000.00
Predollar dividend (all members)	0.086538
Dollar value sold to member X	3640.00
Total paid to member X	315.00
Paid in cash (@ 25%)	78.75
Paid in certificates	236.25

Qualifications to this exemption were included in subsequent Revenue Acts, although federal tax policy on cooperatives has remained fairly constant since 1962. For income tax purposes, federal law permits any firm to deduct from its revenues all operating expenses and any rebates to patrons for which there was a preexisting legal obligation at the time of transaction. Such rebates include per-unit retains or patronage dividends the cooperative had agreed to pay members (or any other patron) for their earlier purchases or sales through the cooperative. That is, net returns on member and nonmember patrons' business the cooperative was obligated to allocate to individual members and other patrons are not taxable to the cooperative. Coops which deduct from reported revenues any per-unit retains or dividends on patronage business are called 'nontax-exempt' cooperatives.

In addition to deducting per-unit retains and returns on patron business, certain cooperatives may deduct stock dividends paid in the current year and any nonpatronage income allocated back to member and nonmember patrons. (Nonpatronage income is an income that is unrelated to the firm's farm supply or product-marking business, for example rental income on the firm's property.) Agricultural cooperatives falling into this 'section 521' or 'tax-exempt' category must, among other restrictions, treat nonmember patrons the same as member patrons in pricing and in equity subscription and retirement plans. Supply cooperatives cannot do more than 15% of their business with nonmember nonfarmers. 'Tax-exempt' status does not ordinarily result in significantly lower income tax than that paid by 'nontax-exempt' cooperatives.

Table 4 shows the tax treatment of a hypothetical multiproduct agricultural supply cooperative that conducts business with members only and has no nonpatronage income. The distinction between tax-exempt and nontax-exempt status makes no difference in the Table 4 example. Tax is paid on unallocated revenue only; income allocated to individual members is not taxed. To determine members' rates of return per unit of patronage, the patronage dividend is first computed as a percent of total member business. That rate of return is then multiplied by each member's total patronage to give the member's total dividend. In the example shown in Table 4, 25% of the dividend is paid to the member in cash and the remainder is held as equity capital, to be redeemed in cash at a later date.

Cooperatives and Economic Performance

Cooperatives have long been regarded as a way in which producers or consumers can substitute for inadequate market services by providing the services themselves. Thus, farmers persuaded that IOF processors pay less than full value for farm products, or charge more than full cost of farm inputs, can form a cooperative to provide the product-handling or input-supply service themselves. Because, broadly speaking, service inadequacy implies and is implied by a departure from competition, such a cooperative becomes a competitive yardstick – a means of both judging how inadequate the IOF performance has been and providing a remedy for that inadequacy. Expressed differently, cooperatives arise and thrive best when markets are missing, namely when the investment climate that would bring forth adequate market services is missing. The competitive yardstick cooperative is, in a stylized way, the traditional open-membership coop because free member entry and exit would eliminate any monopoly elements in the cooperative's own service provisions.

By the same token as profit opportunities grow, allowing markets to become more diversified or competitive, cooperatives begin to compete less successfully with investor-owned firms. This explains why cooperatives tend to play a more prominent economic role in poorer than in wealthier economies and in more socialized than in more capitalist ones. Declining trade barriers during the past four decades, and consequent rising incomes and market globalization, have thus put great pressure on the cooperative business form. Important cooperatives in the US and Europe have become bankrupt or have converted to IOF or semi-IOF form in recent years (Cross *et al.*, 2009). And country-wide cooperative unions in poor- and middle-income nations that once served as agents of government development programs are losing their subsidized status. A prominent example is the National Agricultural Cooperative Federation (NACF) of Korea, which recently ceased subsidizing its farm supply and marketing division with income from its banking division.

Problems with the Cooperative Form

The traditional cooperative's disadvantage in the face of a competitive IOF economy can be traced to four interrelated problems. The first, known as the horizon or liquidity problem, is that – as discussed in the Section Equity Subscription and Redemption – the portion of the member's annual dividend retained as capital stock (withheld patronage dividend) usually is held by the cooperative without interest until the board decides otherwise. The investment often is not revolved back until the member's death. The prospect of this illiquidity discourages membership and hence investment. The second, free-rider problem, is that each member receives the same access to the cooperative's input-supply, -processing, and -marketing services per dollar of his/her patronage, despite that some members have invested more in the cooperative than others have. Newer and smaller volume members typically free ride on the older and larger volume ones, who account for most of the capital trapped in the revolving fund.

Free riding is encountered most likely when coop membership is heterogeneous or the firm operates away from the maximum point on its net average revenue product (NARP) curve. At cooperative volume OC in **Figure 1**, the additional cooperative net margin created by one more unit of raw product is vertical distance OJ (height of the NMRP function above C). If net margins are distributed in proportion to patronage, the same extra unit instead will be paid the greater amount CI (height of the corresponding NARP function). Hence, other members subsidize that last unit by amount JI. Any side payments to nullify such subsidies tend to be divisive. For this reason, a cooperative's success depends partly on the degree of cooperative spirit among the members, including certain individuals' willingness to bear an excess share of the total burden (Cechin *et al.*, 2013).

The third or agency problem is that, on account of the traditional cooperative's one-person-one-vote rule, those with little capital in the cooperative have, besides equal per-dollar benefit of the firm's services, equal control of the policy decisions. This disproportionality between investment and voting power discourages large-volume patrons from participating because the interests of smaller patrons typically differ from those of larger ones (Pozzobon and Zylbersztajn, 2013). Finally, an information or oversight problem is created by the absence of cooperative stock from public exchanges. Public stock prices encapsulate outsiders' judgments about a firm's financial health, which can be used, for example, to determine executive salaries. If such a piece of information is absent, cooperative members must rely on their own direct evidence, such as operating statements and balance sheets, to assess management performance. Perusals of that sort are usually impractical – they involve high monitoring costs.

All four of the above problems arise because member property rights in a cooperative are poorly defined. In particular, the member has an inadequately defined: (1) claim to the cooperative's net income and (2) control over the cooperative's assets – over its investments, contracts, and business policies (Chaddad and Cook, 2004). The control problem is connected, as already seen, to the disproportionality between a member's investment and voting rights (Chaddad and Iliopoulos, 2013).

Analysis of the net-income issue is more complicated. Four aspects of a member's net-income claim (cooperative stock share) can be distinguished: whether the claim is: (1) restricted to member patrons, (2) redeemable from the cooperative, (3) transferrable to other individuals, or (4) appreciable in value. In traditional cooperatives, income claims are restricted to member patrons, redeemable only with board approval, and nontransferable. They also are nonappreciable, that is, their value cannot change with the firm's profitability. The member's property rights are, in short, weak and unclear, severing members' interests from the firm's interests. In most cooperatives, as already seen, a member's net return share is not even held proportionate to his/her share of the firm's capital, although some capital contribution plans do ensure such proportionality.

New Generation Cooperatives

The net result of these difficulties is to discourage investment, undermining the cooperative's ability to grow and compete with other firms. Mathematical models of a farmer's choice between marketing his product through a traditional cooperative and an investor-owned marketing firm underscore this phenomenon. The models show that, as final-product markets become more competitive and the IOF loses its ability to influence prices, the cooperative's competitive yardstick effectiveness in escaping IOF market power declines. Because the cooperative's horizon, free-rider, control, and oversight problems remain, it is motivated to restructure itself into an IOF or move toward bankruptcy (Cross and Buccola, 2004).

As an alternative to such bankruptcy or outright IOF conversion, new cooperative forms have arisen in recent years. Some cooperatives now sell transferrable, appreciable shares to nonmembers and nonpatrons – to business firms in particular – most often through a subsidiary or joint venture. The New Generation cooperative (NGC), found especially in the US and usually engaged in processing and marketing, is particularly important (Cook and Chaddad, 2004; Fulton and Sanderson, 2003; Fulton, 2001; Coltrain *et al.*, 2000). In an NGC, each member's raw product deliveries to the cooperative are determined by a tonnage- and quality-defined contract, expressed as the member's obligation as well as right and combined with his/her obligation to purchase a particular number of capital shares. Such shares can be sold to, or purchased from, other members or nonmembers.

Thus, the membership in the new generation cooperative is closed, as distinguished from the open membership in most traditional cooperatives. Identity of each member's raw product typically is preserved in the course of processing and sale, so patronage dividends paid to each member are specific to his/her own delivery lots. Consistent with cooperative principles, ownership is thus linked to patronage but, as with larger investor-owned firms, rights to such ownership can freely be bought or sold. And consistent with the worldwide trend toward identity-preserved niche marketing, emphasis is placed on quality- and time-specific delivery contracts between member and cooperative.

In contrast to the traditional cooperative's open-membership policy, successful raw-product value enhancement in an NGC involves restricting membership. Closed membership is essential for maintaining a volume low enough to capture the extra-competitive profit afforded by the firm's quality, reputation, and marketing niche. These gains accrue to the cooperative's farmer members in the form of extra-competitive returns to the members' fixed farm and cooperative assets. In a social welfare sense, the supernormal returns can be justified by the special quality, service, or innovation in the NGC's product, which a perfectly competitive commodity market could not offer. Under open membership, those gains instead would attract new members, whose additional supply would drive final product prices downward. But the New Generation cooperative form has drawbacks as well. The goal of maximizing the return to equity is often inconsistent with the goal of maximizing the return to patronage. Improving equity returns may, for example, require buying raw product on the open market at the expense of processing the cooperative members' own farm goods. Because the NGC seeks to enhance the return to member equity as well as to member patronage, a tension is created between these two goals (Kalogeras *et al.*, 2013).

Solution of the control problem in cooperatives is also often difficult. In the US, incorporation laws in most states require cooperatives to guarantee one vote to each member in Board elections, preventing any proportionality between control and capital investment. As a partial solution to this problem, and to provide the external oversight available to publicly traded firms, some cooperatives – especially in Northern Europe – employ a Board of Commissioners in addition to a Board of Director's (Hendrikse, 2004). Commissioners, selected from outside the cooperative, have some influence over Director's decisions. Regardless of board's decision structure, members lose control over their cooperative as it grows because growth requires delegating power to management. From a control perspective, indeed, very large cooperatives closely resemble very large investor-owned firms.

Cooperative as Social Transformation

An alternative to providing members more well-defined property rights is to shift away from rather than toward such rights. In particular, some analysts view the cooperative form not as one element of a competitive market (the competitive yardstick school) but as an alternative to capitalism. They argue that, in the absence of a fully cooperative economy, IOFs will pay farmers below-competitive prices and charge consumers above-competitive ones. Cooperative organization of production and distribution would bring a more just society, in which communities are united and beyond selfishness. This thinking was an important element of the 'cooperative commonwealth' movement of the early twentieth century, associated with organizer and theorist Aaron Sapiro.

Among its modern heirs is the United Nations, which, in its declaration of 2012 as the International Year of Cooperatives, said cooperatives will "not only [promote] better business but advance sustainable development … and promote equality and social integration." The UN and its partners promote and raise awareness of cooperatives by holding public forums and advocating government policies conducive to cooperative growth. They see cooperatives as a move toward 'social, economic, and environmental sustainability,' and call for a 'paradigm shift for economy and social inclusion.' The International Cooperative Alliance, a consortium of member nations' country-wide cooperative unions, is a prominent example of this movement. Like the Sapiro cooperatives of the early twentieth century, its emphasis is on training, promotion, and political action rather than on strengthened property rights, and on more expansive cooperative goals rather than the more specialized ones in a New Generation cooperative.

Universal cooperative organization is unnecessary for, and likely would prevent, the maintenance of competitive prices. Models suggest that even the threat, let alone presence, of a cooperative's entry into an imperfectly competitive IOF market is especially effective in moving consumer prices toward the competitive norm (Sexton, 1990). An IOF considering entry into an agricultural processing market recognizes its new presence may boost raw product prices and reduce final-product prices, both of them impairing its likely profit. The cooperative entrant worries only about its potentially depressing influence on final-product prices because any raw-product price change would be passed on to farmer members in the form of higher farm revenue. Thus, the threat of a cooperative's entry is more credible than of an IOF's entry, implying that the freedom to form a cooperative is an especially potent force toward market efficiency.

Summary

The cooperative or user-owned way of organizing an agricultural services firm is fundamentally different from the investor-owned way. In the former, net returns are paid to the farm products supplied to or inputs purchased from the firm. In the latter, net returns are paid to the capital. Efforts to keep cooperative members' capital investments proportionate to the values of their product supplies or input purchases are difficult to implement. And their implementation moves the organization in the direction of an investor-owned model.

Because a farmer's products and input uses are far less mobile than his/her capital potentially is, user-based control of a services firm is much less flexible than capital-based control. Farmer capital can quickly be moved from Brazilian sugar refining to Canadian phosphate mining. The farm's own sugarcane production and phosphate use cannot. This difference lies at the heart of the allocative inefficiencies to which cooperatives are prone, and explains why cooperatives tend to fail when investment markets are widespread and liquid.

Such a competitive ideal can, however, never be fully realized in given situations. Regulation often pushes prices above the competitive norm or below what attracts enough supply. The scale of investor-owned marketing or input services often is inadequate, especially in low-population areas or, especially, when the services are new, innovative, or specialized. Cooperatives then arise to protect members from these government and capital failures.

Yet the cooperative itself is an element of the market system, as one can see from the coop's enhancement of competition even in the face of being injured by it. The rise of vertical integration – a contract-specific relationship between two firms that bypasses the more anonymous marketplace – is a case in point. Being supplier- or buyer-owned, a cooperative is itself an instance of vertical integration and therefore a natural part of market development. Governments' declining use of cooperative federations as agents of farm subsidies more likely underscores this essentially market nature of cooperative organization.

Glossary

Analytical agricultural ethics The review and investigation of concepts, arguments, and implicit norms as they are deployed in developing an understanding of agricultural practice.

Burdens of proof The criteria that must be met for a particular ethical judgment to be made or reversed.

Communitarianism A philosophical approach that emphasizes the importance of tradition, the fundamental role that a society plays in forming political and moral reasoning, and the slow change of culture.

Consequentialism A philosophical approach that stipulates that all human actions be justified solely in terms of their consequences or effects on others' welfare.

Ethical reductionism A philosophical approach where ethical concepts are reduced to statements about individual and subjective experiences; it promotes a strong division between fact and value.

Ethics The systemization and defense of values, standards, and conceptions that are used to make ethical judgments regarding human conduct.

Food deserts Urban areas with limited access to nutritious foods that are often disproportionately made up of poor socioeconomic classes and minority communities.

Food security The establishment of market-based mechanisms meant to ship food to other areas experiencing scarcity.

Food sovereignty A broader conception of food that moves away from market-based systems where human rights concerns are bound up within the food systems themselves.

Informed consent Occurs when parties (that must bear risks) voluntarily agree to do so under conditions of full disclosure; when informed consent is lacking, even low-level beneficial risks may be rejected.

Justice The terms 'ethics' and 'justice' are often used interchangeably, as there is no standard method to distinguish between the two. However, justice is commonly defined in two ways within philosophical traditions. First, traditional philosophers, such as Plato, used the word 'justice' to indicate a personal or individual virtue. Second, philosophers such as John Rawls and Ronald Dworkin argued that the locus or the appropriate place of justice is the social institution or structure of society. This second definition of justice is most widely held today.

Liberalism Although there are many forms of liberalism, in general liberals hold the view that liberty is the attribute of primary political value. In addition, current forms of liberalism largely accept the view that the locus or the appropriate place of justice is the social institution or structure of society.

Metaethics A branch of ethics that attempts to understand the epistemological, psychological, and semantic presuppositions of ethical properties, attitudes, and judgments.

Neoliberalism A form of liberalism that promotes the use of a largely unregulated market system to distribute goods.

Practical ethics The application of values, standards, and conceptions used to make ethical judgments to real life situations. This also includes the abstraction of ethical principles from specific contexts.

Reductionism The reduction of a complex system or set of phenomena to a formal set of interrelated rules.

Rights The justified or enforceable claims that may be made on behalf of right-holding parties; it is typically thought to provide absolute protection of individual interests against social benefits.

Scientific reductionism The reduction of a system or complex set of phenomena to a set of rules solely based on scientific principles; for example, one could reduce the functioning of the human organism to chemical principles and completely disregard psychological principles.

Substantive agricultural ethics Prescribes specific action plans, practices, and policies for persons and organizations involved in agricultural issues; its aim is to present arguments for or against a proposed course of action that applies those concepts, rules, and standards with clarity, rigor, and logical coherence.

Utilitarianism A nineteenth century approach to ethics that has greatly influenced the twentieth century public policy, particularly in the arena of cost–benefit and risk–benefit management; the term was first used by Jeremy Bentham and then by John Stuart Mill. The Utilitarian maxim states that the correct action is the one that produces the greatest amount of good for the greatest number of people.

Introduction

The word ethics is often used interchangeably with the word morality to indicate goals, norms, and values that are taken to guide human action. A common, but far from universal, distinction is to define ethics as the systematic study of moral codes, particularly with regard to criticism, justification, and acceptability of social norms. As critical evaluation of moral norms itself implies the application of norms; scholarly work on ethics has perennially been accused of circularity, dogma, relativism, and begging precisely the question it attempts to answer. Scholarly study of morality has, nevertheless, made it

possible to provide considerably more explicit, locally coherent, and rigorous arguments on goals, norms, and values than are typically found in ordinary life.

Agricultural ethics is the criticism, analysis, and justification of systematic moral codes and the acceptability of social norms that exist or are applied to practices of food and fiber production, distribution, and consumption. Given this definition, agricultural ethics can be understood as an interdisciplinary research and education area. Research and teaching on ethics take place to some degree in all disciplines of the social sciences and humanities, although some practitioners of these disciplines have disavowed work on ethics. The most typical disciplinary home for work in ethics has been philosophy, although departments of theology, religious studies, and political science also typically have specialists in ethics. Recent work in agricultural ethics emphasizes (1) unintended health, safety, and environmental impacts of agricultural technology; (2) the structure of agriculture, including distribution of benefits from agricultural production; and (3) questions of conduct, character, and professional ethics. In addition, special attention has been given to the moral standing of agricultural animals and to ethics as it relates to agricultural biotechnology. Depending on the ethical framework utilized by specific theorists working in this field, the above topics can also be framed as justice issues. As is illustrated below, the ethics of agriculture and justice are tightly linked.

Agricultural Ethics

Broadly speaking, ethics (also known as moral philosophy) is the systemization and defense of values, standards, and conceptions that are used to make ethical judgments regarding human conduct. Ethicists study how people should act and ethical norms are understood to be implicitly found within cultural practices, grounded in psychology, and able to be discovered through reason. Here ethical norms are understood to be an accessible part of the world. This branch of philosophy can, roughly, be divided into three major areas: metaethics, normative ethics, and practical ethics. Metaethics attempts to understand the presuppositions and logical structure of ethical properties, attitudes, and judgments (Sayre-McCord, 2012). This branch can be understood as a broader (or meta) analysis of ethics. In contrast, normative ethics is the development of general principles or standards that make particular actions 'right' or 'wrong' and the creation of theories that explain why some choices are better than others. This branch of ethics maps on well to the general definition given above and is often what is meant when the word 'ethics' is used without qualification. Engaged or practical ethics also focuses on determining right action but specifically with respect to real life situations. Sometimes engaged ethics not only involves the application of ethical theories to particular cases, but it also includes the derivation of ethical norms from specific contexts and integration with factual matters that can significantly influence the content and meaning of a normative claim or judgment.

Although metaethics is an important subfield, normative ethics and engaged ethics are of particular importance for those attempting to better understand agricultural science, technology, and farming methods. The following two methodological approaches are common in agricultural ethics. Analytic agricultural ethics undertake review and investigation of concepts, arguments, and implicit norms as they are employed in developing an understanding of agricultural practice, its goals, and the secondary social and environmental consequences of food and fiber networks. Analytic ethics aim to improve understanding of concepts, rules, and standards that are commonly used to frame and defend moral judgments and prescriptions for action. Substantive agricultural ethics prescribe specific action plans, practices, and policies for people and organizations involved in agricultural issues. The aim of substantive ethics is to present arguments for or against a proposed course of action that applies those concepts, rules, and standards with clarity, rigor, and local coherence.

Agricultural Ethics and Justice

It is important to note here that the terms 'ethics' and 'justice' are often used interchangeably, as there is no standard method to distinguish between the two. For example, sometimes 'ethics' and 'justice' are used to mark a distinction between personal conduct (ethics and morality) and the norms or standards that should govern the structure of the societies and the political life (justice or social ethics). There is also a broad distinction between justice as administered by courts of law and social justice, or just, fair, and morally defensible social arrangements. Traditional philosophers, such as Plato, might have used the word 'justice' to indicate a personal or individual virtue, but the broad philosophical interest in liberty (usually referred to as 'liberalism') that swept Europe during the eighteenth, nineteenth, and the twentieth centuries now dominates most discussions of social justice, even for those who wish to contest or critique the liberal approach.

In contrast to individual conduct, philosophers such as Rawls (2001) and Dworkin (1996) argued that the locus or the appropriate place of justice is the social institution or structure of society. Roughly, liberal philosophers identify liberty as the attribute of primary sociopolitical value (Cranston, 1967) and thus consider institutions (or rules) that protect it 'normatively basic' (Gaus, 1996). For liberalism, the product of a properly set up political structure is a just society. The central question then involves deciding whether or not laws are justified in limiting the personal liberty of citizens. Examples of fundamental rights commonly supported by liberalism include free trade, freedom of religion, and private property, as these universal rights are believed to promote personal liberty (Gaus and Courtland, 2010). The question of whether an agricultural practice (such as a specific pesticide) is to be banned qualifies as a case in point, because the ban will limit a given farmer's liberty by constraining the choice of technologies that can be used. Thus, as there is no standardly recognized method of drawing a distinction between ethics and justice, many ethical issues in agriculture can also be understood as justice issues.

History of Agricultural Ethics

Normative or ethical implications of agriculture were a common topic for scholars of philosophy, society, and biology for

most of the 3000-year history of Western thought. Aristotle discussed the configuration of agriculture he thought necessary for fulfilling human promise. More recently, Thomas Jefferson was both a scientifically informed practitioner of agriculture at his Monticello plantation and a philosopher of agriculture who contributed enduring analysis of how farm structure is related to problems of governance in a democracy.

Ethical reflection on agriculture carried over into the twentieth century through the efforts of scientists and agricultural leaders, such as Liberty Hyde Bailey and Henry Wallace, but the systematic discussion of agriculture was virtually absent in the writings of the late nineteenth and twentieth century philosophers and moralists. The last generation of philosophers to discuss agriculture as a philosophical topic is the one that included John Stuart Mill, Ralph Waldo Emerson, and Karl Marx. Each of these three authors wrote extensively on agriculture, but no one recognized as a leading contributor to philosophical or religious ethics since them has done so.

After World War II, agricultural scientists and leaders gave little systematic attention to ethical issues. Agricultural ethics was not included in the curriculum of agricultural colleges. Ethics became increasingly marginalized though in the 1950s and 1960s, with only a handful of social scientists undertaking normative evaluation of agriculture. Even in these studies, the role of ethics was largely implicit in that the norms or values on which evaluations had been based were seldom stated and almost never defended on philosophical grounds. Significant exceptions to this rule can be found in the work of agricultural economists John Brewster, Harold Breimyer, and Glenn Johnson. These works were almost totally ignored by professionals in liberal arts disciplines, such as philosophy, religious studies, and political science. Indeed, the decline of attention to ethics in agriculture reflects a general decline in attention to ethics throughout all departments of universities in the decades following World War II.

In 1962, Rachel Carson published Silent Spring. Although it was not in itself a philosophical book, Carson's critique of agricultural chemicals was arguably the first in a series of criticism of the agricultural practices that had emerged following World War II. Frances Moore Lappe's Diet for a Small Planet; Jim Hightower's Hard Tomatoes, Hard Times; Wendell Berry's The Unsettling of America; and the republication of Walter Goldschmidt's 1947 study As You Sow were among the most influential and most enduring of critical works published before 1980. Books by critics of agriculture have since proliferated, with at least a dozen published every year in the decade between 1982 and 1992. Although these books seldom present rigorous empirical or philosophical arguments for their conclusions, they typically make an explicit statement of the goals, values, and norms on which their evaluations of agriculture depend. They have in this way provided the source material for a resurgence of interest in careful scholarly attention to the philosophical foundations of agricultural practice.

As public criticism and mistrust of agricultural practices grew under the influence of these critics, agricultural institutions showed a renewed interest in the study of agricultural ethics. Courses were offered in some agricultural colleges, and a limited amount of research by philosophers and social scientists had been undertaken. Ethics and values issues have also become topics for symposia at disciplinary meetings of agricultural scientists and at consensus conferences intended to establish priorities for research and for policy change. Attempts to extend work on ethics to producer groups have thus far been limited. Although agricultural ethics remain somewhat marginal in the agricultural disciplines, the role of ethics in curriculum, research, and public policy has been increasingly accepted. Today both analytic agricultural ethics and substantive agriculture ethics are blooming with many agricultural ethicists making use of historical ethical frameworks, such as (1) rights-based ethics, (2) consequentialism, (3) communitarianism, and (4) environmental ethics.

Rights-Based Ethics and Agriculture

Rights-based ethics enter into issues surrounding agriculture and food systems when the implementation of new technologies or new policies is thought to violate the basic rights of individuals. In many cases, economic or governmental power is marshaled to deny particular groups civil rights, such as insuring a group's physical or mental integrity, life, and safety. There is little doubt that the historical industrialization and consolidation of agriculture and food production systems (such as the initial implementation of animal slaughtering technology and confined feeding operations) were accompanied by violations of civil liberties. For example, in the 1906 novel The Jungle, Sinclair (2012) graphically portrayed the lives of immigrants working in the early Chicago meatpacking industry, illuminating the poor working conditions, exploitation, and unnecessary hazards experienced by the workers. Such conditions would clearly be labeled unethical from a rights-based approach. Today similar arguments have been made regarding the conditions faced by workers in current meatpacking operations and migrant and seasonal farmworkers.

In addition to ethical issues surrounding the civil rights of workers, Schrader-Frechette (1999) argued that the violation of the basic rights of individuals can also occur where risks are not voluntarily chosen but involuntarily imposed. Examples of this could include food safety policy, if the consumer is not involved in the process of forming this policy, as each time a person consumes a food product there is a slight risk that they will get a foodborne illness. In addition, if specific groups or subgroups of the population, such as minority communities or those of low socioeconomic classes, suffer from a lack of access to quality food, then this could also be considered a violation of their rights, as they are not equally benefiting from the food system and, in some cases (such as when these groups make up the majority of the workforce employed in agriculture and food processing), are forced to take on a disproportionate share of the risks associated with the production of food.

The framing of food access as a justice issue and violation of rights is gaining steam in both society at large and some academic circles. For example, as Schanbacer (2010) argued, some development scholars focused on combating hunger are moving away from a call for food security – or the establishment of market-based mechanisms meant to ship food to other areas experiencing scarcity – and instead advocating food sovereignty or a broader conception of food where human rights concerns

are bound up within the food systems themselves. Here 'food security' should be understood as a policy with an aim of ensuring food availability for purchase, whereas food sovereignty connotes an entitlement (or positive right). In addition, local food justice movements, made up of active citizens, are working to combat 'food deserts' or urban areas with limited access to nutritious foods that are often disproportionately made up of poor socioeconomic classes and minority communities. These areas often lack grocery stores, farmer's markets, and other distribution points for nutritious foods.

Consequentialism and Agriculture

The primary philosophical opposition to rights-based ethics comes from those who espouse an ethical approach referred to as 'consequentialism.' Consequentialism stipulates that all human actions need to be justified solely in terms of their consequences or effects on others' welfare. The most popular form of this ethic is commonly labeled 'utilitarianism,' after the works of Jeremy Bentham and John Stuart Mill gained prominence during the eighteenth and nineteenth centuries. According to utilitarianism, the evaluation of these consequences include the following mandates: (1) it must be comprehensive or include all parties affected and all effects, (2) it must be additive or its benefits and harms need to be able to be summed up, (3) it must be comparative or include the comparison of possible consequences from alternative actions, and (4) it must be optimizing, or the appropriate action must produce 'the greatest good for the greatest number' (Sen, 1987). Utilitarian ethical approaches closely correspond to common quantitative tools of analysis developed by welfare economists, such as probabilistic risk analysis and cost–benefit analysis. Such tools have been used by the United States during the process of siting hazardous waste facilities. However, it is important to note that these tools are not, in themselves, prescriptive.

The work of the Nobel laureate in economics Amartya Kumar Sen has had enormous influence on utilitarian approaches in domains of crucial importance for agriculture, economic development, and natural resource management. Sen (2000) began by pointing out frequently overlooked inconsistencies in utilitarian interpretations of social welfare but moved on to develop his 'capabilities' approach that combines some of the ethical insights and strengths of rights theory with a social choice framework that allows utilization of the analytic tools that had been developed by economists working with utilitarian ethical assumptions. Succinctly, the capabilities approach uses economic tools to analyze policy alternatives, but instead of optimizing wealth or social utility, it recommends a focus on people's capabilities or, as Sen had said, 'freedoms' (Sen, 2000). Thus, the capabilities approach brings economics-based policy analysis broadly into conformity with conceptions of justice advocated by John Rawls (Sen, 2009).

Communitarianism and Agriculture

Another ethical approach, specifically communitarianism, is increasingly entering into issues surrounding agriculture and food systems. In sharp contrast to liberalism, communitarians emphasize the importance of tradition, the fundamental role that society plays in forming political and moral reasoning, and the slow change of culture (Bell, 2012). Modern versions of this ethical theory largely began as critiques of John Rawls' political philosophy, which emphasizes the role of an individual in society and includes the assumption that the purpose of the state is to secure liberty and fairly distribute resources. Both of these attributes have been contested by communitarian philosophers, such as MacIntyre (1984) and Sandel (1981). For example, Alasdair MacIntryre argued that a morally right action should be understood in terms of virtues that are grounded in the community's conception of right conduct. For communitarians, principles of justice must be found in the traditions of specific societies and thus are not universally applicable. However, it should be noted that a communitarian may object to the use of liberal terms here, as they argue that these may promote selfish behavior.

In addition, communitarian philosophers, such as Sandel (1981) and Taylor (1989), argued that a person is largely constituted through community attachments, such as family ties, localities, and religious traditions. This conception of the self is in sharp contrast to the overly individualistic liberal conception of the person; a person who attempts to push for solely selfish interests. Communitarian ethics are relevant to food and agriculture because many traditional agricultural societies have articulated both cultural identity and moral responsibilities through norms that emerge out of longstanding farming practices and attachments to the land. Smith (2003) argued that Wendell Berry, a well-known critic of industrial farming practice, had a fully developed political ethic based jointly on a communitarian ethic and a deep suspicion of the impact that industrial technologies had on farm households and rural communities.

Some contemporary food-oriented social movements appear to be motivated by communitarian ethics. Individuals and groups combating food deserts not only conceive the lack of access to fresh fruits and vegetables as a justice issue but also often have deep commitments to their specific community. Many of these groups argue that common strategies used to fight food deserts, such as creating neighborhood gardens, not only address problems surrounding food access but also serve as a way to empower individual communities through the development of small scale, embedded economies, and combat implicit racism in the food system. Another strategy or goal of these organizations is to reconnect fellow community members to their food traditions. Similarly, local food scholars, such as DeLind (2011), argued that the local food movement (which is similar but distinct from food justice movements) is as much about place making and community building as it is about securing food access. She writes that local food is both a "part of a regenerative agrifood system... [and] also about restoring 'a public culture of democracy' and engaging in the continual creation, negotiation, and re-creation of identity, memory, and meaning" (p. 279). Thus, both food justice movements and local food movements appear to be deeply grounded in communitarian principles, such as a commitment to and cultivation of community, the importance of culture and tradition, and the conception of the self as embedded within a specific context.

Environmental Ethics and Agriculture

Similar to the communitarian view that principles of justice must be distilled from the traditions of specific societies, those involved in local food movements often conceive of food systems as dynamic (or connected to politics, history, and ecology) and place based (Dahlberg, 1993; DeLind, 2011). Although this ethical approach is similar to communitarianism, it is distinct due to the fact that the understanding of who or what is an 'ethical patient' has been broadened to include the surrounding ecosystem, biotic communities, and nonhuman animals. Ethics such as these are often generally labeled as 'environmental ethics' or 'ecological ethics.' Food or agricultural ethics can be understood as one subfield in environmental ethics, as these ethics often take the ecosystem into account due to the fact that food production is inexorably tied to the environment. In addition, environmental ethics come in many forms, as they often include aspects of classical positions, such as rights-based ethics and consequentialism, and more radical conceptions of what it means to be an ethical or just human being.

For example, according to Warren (2000), environmental ethics can be roughly divided into four categories: house positions, reformist positions, 'mixed reform and radical' positions, and radical positions (p. 77). House positions are ethics that use mainstream or classical arguments, such as consequentialism, but apply them to the environment. These arguments are 'housed within' the larger ethical traditions that they draw from. Reformist positions reevaluate key assumptions built within classical ethical arguments and reform or revise them so that the environment becomes morally considerable. Regan's (2003) work on animal ethics is a prime example of a reformist environmental ethic. 'Mixed reform and radical' ethics are those that not only utilize aspects of reformist ethics but also incorporate new or radical ideas into the ethic (p. 82). According to Karen Warren, this includes the work of Leopold (1966) and Thoreau (2004). Finally, radical positions are environmental ethics that introduce new considerations into the ethical dialog. This category includes such ethics as bioregionalism, social ecology, ecological feminism, and deep ecology.

Several of these environmental ethics are increasingly entering into issues surrounding agriculture and food production. For example, environmental impacts of industrial farming practices and confined feeding operations (CAFOS) that affect surrounding populations are often critiqued using various environmental ethics, such as house ethics based on utilitarianism or rights-based approaches and more radical forms, such as deep ecology and ecological feminism. In addition, the specific treatment of animals within agriculture is another area where such ethics have been used to defend changing husbandry practices, such as arguments for the inclusion of enrichment activities in CAFOS and the requirement that chickens be stunned before slaughter. In addition to arguments based on efficiency and cost–benefit analyses, environmental ethical arguments are increasingly prevalent during food and agriculture policy formation, especially when boards decide on or edit standards meant to ensure the ethical or just use of nonhuman others, the environment, or what levels of environmental impacts are morally acceptable.

In addition, many of these ethics and competing conceptions of justice are being blended and incorporated as citizen movements apply them on the ground. For example, as partially illustrated above, the local food movement utilizes communitarian, rights-based, and radical conceptions of justice. It utilizes communitarianism due to the fact that, within this movement, people are understood to be deeply imbedded in local contexts and just actions, be that to others or to the land, can be distilled from the traditions of specific societies or traditions. It utilizes an expanded liberal conception of justice, as it includes a mandate for the just distribution of resources. Finally, it also incorporates radical conceptions of justice, as it expands the sphere of moral patients to include the surrounding environment, and conceptualizes food systems as 'regenerative' or guided by principles of ethics, equity, and ecology. Thus, ethics and understandings of justice are not static but are social constructs and are thus constantly in the process of transformation and change.

Although an understanding of agricultural ethics can be gained through the analysis of the ethical frameworks utilized by the field, it is important to recognize themes emphasized by recent work. Such themes include (1) unintended health, safety, and environmental impacts of agricultural technology; (2) the structure of agriculture, including distribution of benefits from agricultural production; and (3) questions of conduct, character, and professional ethics. These themes form the topics of the following sections.

Unintended Consequences

Many criticisms of modern agriculture have noted unwanted and unintended consequences of agricultural chemicals. Pesticides have had documented effects on wildlife populations, and some are known carcinogens. Nitrogen fertilizers can pollute groundwater and surface water. Many agricultural chemicals have long been known to have toxic effects when improperly handled, stored, or applied. It is clear that neither manufacturers nor producers intended or wanted these consequences, and both groups have made efforts to mitigate and control unintended consequences. Nevertheless, unintended consequence of agricultural chemicals pose ethical problems in that it is impossible to eliminate the risk of an unwanted event entirely. Furthermore, there is often disagreement about the degree of risk associated with agricultural chemicals. Some individuals express far greater concern about exposure to pesticides than others. Producers, scientists, and chemical manufacturers thus face the problem of managing concern for unwanted effects, even when the empirical evidence for such effects is scant, controversial, and even nonexistent. Whether real or imagined, unwanted consequences of chemical have significantly affected the reception of many agricultural technologies, including mechanization and biotechnology, among producers and food consumers since 1962.

An analysis of ethical issues associated with unintended consequences surveys the assumptions and implicit norms that have guided action contributing to the unintended outcomes. Public claims expressing a rationale or justification of such action are scrutinized, and the pattern of reasoning is exposed. In many cases, disagreement over agricultural

practices can be traced to incommensurable assumptions in the way that antagonists view the world and the relation of moral norms to human action. This is a disagreement that is both more subtle and more long lasting than simple disagreement over values. Alternative approaches to the problem of unintended consequences provide an example. Many people, especially those associated with the agricultural sciences, exhibit behavior and speech that is most consistent with the utilitarian approach to ethics outlined above. Environmentalist, agrarian, and consumer critics have rejected this basic approach, sometimes assuming a pattern of thought more consistent with rights.

The utilitarian strategy adopts an ethical norm that requires decision makers to anticipate the consequences of their actions and policies to the fullest extent possible and to weigh the costs associated with unintended consequences against the acknowledged benefits of technology accruing in the form of increased food availability, increased profitability of farming, and decreased consumer food cost. This strategy presents a series of methodological and philosophical problems, in that unwanted costs are often difficult to quantify, and in that there are philosophical disagreements over when to accept trade-offs. A severe distributive inequality, for example, might provide a reason to reject technologies that clearly produce more aggregate benefits than harms.

A rights-based strategy assumes that individuals may be accountable for predictable, although unintended, consequences of their action. Rights provide criteria for accountability because acts that do not interfere with others' rights are judged ethically permissible. When individuals and organizations act within their rights, their actions are ethically acceptable without regard to whether they optimize the trade-offs of cost and benefit. However, virtually all of the unintended consequences associated with agriculture constitute interference in some form. A strict application of rights constraints implies that all such actions should be prohibited. A more adequate determination of accountability requires one to see that many individuals have acted in ways that collectively produce the unintended consequence. Hence, the accountability of individuals and groups depends on how their activity is related to the activity of others who may share or wholly assume responsibility for consequences.

In application, the rights approach to agricultural ethics often establishes burdens of proof that must be satisfied before an action is undertaken, rather than absolute constraints. A burden of proof is a criterion that establishes which party can be held accountable for consequences. A key burden of proof in evaluating unintended consequences is informed consent. Individuals who use an agricultural technology or product under conditions of informed consent can be understood to have accepted responsibility for the consequences of use. Scientists, extension agents, and private sector firms that introduce technology under conditions that secure the informed consent of affected parties satisfy ethical norms and may not be held accountable for unintended consequences. The criterion of consent transfers accountability to the affected parties. Consent criteria present a series of philosophical problems not unlike utilitarian approaches, in that the conditions for expression of consent are complex. Consent implies that people have meaningful options, that there are commonly recognized practices that imply consent, and that those giving consent have full knowledge of the unintended consequences that might ensue. As such criteria are seldom fulfilled completely, burdens of proof are often satisfied in the same idealized fashion that utilitarians perform optimizing calculations.

Although both strategies are idealizations, each establishes a general conceptual approach to problems in agricultural ethics at cross purposes with the other. The utilitarian strategy begins with an assessment of the likely consequences associated with an agricultural technology or practice. In the case of a chemical pesticide, the consequences would include risks to the health of farm labor and to food consumers as well as benefits to producers in the form of increased profitability. If a proposed activity has a significant impact on consumer food prices, it will be important to anticipate indirect effects on the availability of food for the poor. When all the relevant consequences have been assessed, the proposed activity can be compared with one or more alternatives. As a minimum, alternatives include simply using and not using the proposed pesticide, but the array of possible strategies for use is always complex, include licensing for restricted versus general use, notification, rules that may or may not be included, etc. The comparison allows one to make a fairly sophisticated judgment about the trade-offs between two choices.

Trade-offs themselves can be complex. A simple-minded decision rule for utilitarian ethics is to allow an action whenever benefits outweigh costs, but there may be alternatives that produce a more attractive ratio of benefit to cost. One may also face a choice between one option that has a high benefit to cost ratio, yet returns few fatal benefits, and another with a less attractive ratio of benefit to cost that produces more benefits (at higher costs). Distributive issues also make trade-offs difficult to compare. For example, one chemical may pose a low-level risk of cancer to many food consumers, whereas another may pose little or no risk to consumers but may be far more dangerous to handle in the field. One may thus be comparing a low-level risk to all food consumers against a high-level risk to a small group of agricultural labors. A question of fairness arises, particularly if the laborers are comparatively less well-off as a group than food consumers. Here costs (in the form of risk) are not comparably distributed by each option.

The alternative strategy for dealing with unintended consequences would approach the decision to use an agricultural chemical by examining a series of burdens of proof. Here the beginning assumption is that agents are responsible for unintended consequences of their action. However, a manufacturer of a chemical may shift responsibility to the actual users of the chemical, provided that criteria for informed consent have been met. Similarly, a producer may shift responsibility for unintended consequences to employees or consumers when these groups are informed of the potential consequences and when they have meaningful opportunities to make alternative choices. On this view, the residue of agricultural chemicals poses no ethical problem as long as consumers have both a reasonable opportunity to get information about unintended consequences and an alternative choice in the form of organic foods. If these conditions are met, then there may be chemical residues, and consumers have

to bear the responsibility for any consequences for their choice of foods.

The burdens of proof that must be met in developing and promoting an agricultural technology may seem heavy when described abstractly. In practice, they are consistent with the general structure of a free market economy, provided that two conditions are met. Sellers must provide full information, and sellers' economic power must not become so concentrated that buyers are effectively denied a meaningful opportunity to choose alternatives. It is important to note that consent criteria do not necessarily produce a socially optimal outcome from a utilitarian perspective. One reason it may not is that buyers may have faulty preferences. They may, for example, choose foods that are unhealthy, or they may place too much emphasis on immediate gratification. Many economists assume that consumers' actual preference constitute the norm for determining a social optimum. If immediate gratification and consumption of unhealthy food are defined as a benefit in virtue of the fact that such activities satisfy consumer preferences, there will be less divergence between utilitarian and consent criteria than would be the case when costs and benefits are defined according to criteria that are independent from existing preferences.

The economic concept of market failure is also an instance where consent and utilitarian criteria diverge. Resource economics identifies a number of situations in which buyers and sellers making voluntary exchanges will reach outcomes that all would regard as suboptimal. The American dust bowl has frequently been analyzed as an instance of market failure. Under utilitarian criteria, market failure provides a justification for regulation, the coercive application of state power to ensure that individuals and organizations do not engage in practices that produce the unwanted outcome. Such state actions can come into direct conflict with ethical criteria associated with property rights. The result is a philosophically based political conflict between those who advocate such action on the part of government as a violation of consent criteria implied by common notions of property rights.

Structure of Agriculture

Ethical issues associated with the structure of agriculture overlap with those of unintended consequences to the extent that changes in the size distribution or number of farms can be understood as an unwanted consequence of technological change. The general relationship between means of agricultural production and norms for land entitlement and property rights has, however, been an enduring philosophical question. As noted above, Aristotle thought that achievement of moral virtue among the elite of society depended on a release from labor of agricultural production that could only be provided through a system of agricultural production based on human slavery. In the eighteenth century, John Locke defended the enclosure movement that removed English lands from common pastoral use and converted them into privately controlled croplands on the grounds that enclosure returned far more benefits in the form of increased food availability. At about the same time, Jean Jacques Rousseau argued that the primary impact of privatization of agricultural lands was to create scarcity, by creating a privileged class of land-holding aristocrats.

This pattern of divergent philosophical views has continued. Some, such as economist Luther Tweeten, evaluate changes in the distribution of farms by size and by type of ownership in terms of criteria that stress efficiency and aggregate benefits of farm production. Others, such as sociologist Jack Kloppenburg, stress how changes in agricultural practice have favored the interests of a few influential individuals generally working behind the scenes.

The dispute is particularly relevant for planning and evaluating agricultural development. Agricultural development programs, such as the Green Revolution, have been based on the view that carefully managed increases in agricultural productivity are a necessary condition for improved conditions in the developing world. On the opposing view, dependency theorists have argued that underdevelopment has been caused by exploitative encouragement of sugar, tobacco, coffee, tea, and other stimulant production in developing countries as well as production of 'luxury' crops, such as fruits, oilseeds, and spices. This group sees little hope for development until the developing world's cycle of dependency on developed countries (first for production technology and expertise, then for export markets) is broken.

One way to analyze the contrast between the two philosophies is to return to the distinction between utilitarian and rights-based ethics. On a utilitarian view, changes in farm structure create costs in the form of financial and emotional consequences for those who exit farming. There may also be more abstract costs in the form of esthetic and historical values associated that like a given farm structure or broader patterns of culture. The key question is whether production efficiencies achieved through new technology and the resulting farm structure produce benefits that outweigh these costs. For a rights theorist, the comparison of cost and benefits is largely irrelevant. The key question is whether affected parties were adequately involved in the events that cause a change in structure. Dependency theory, for example, may be interpreted as resting on the claim that affected parties in the developing world have been denied any meaningful opportunity to reject the offer of Green Revolution technology. Hence, the resulting changes in farm structure do not satisfy burdens of proof that relate to participation, representation, and consent of affected parties.

It is most likely that those who defend the record of change in farm structure would be willing to accept a utilitarian characterization of their ethical rationale. Luther Tweeten has done so explicitly. Some critics would base their objections on rights claims, whereas others diagnose a more fundamental problem. Like utilitarians, critics such as Kloppenburg or Wendell Berry (discussed below) would concentrate on the consequences of farm structural change. They would, however, argue that the relevant consequences are far more comprehensive and systematic than utilitarian defenders have recognized. This form of criticism has emphasized the reductionism implicit in the defense of the status quo, a tendency to evaluate action in terms of criteria that fail to account for holistic or systematic effects.

Reductionism is seldom defined precisely in critics' writings. Two themes that recur are scientific reductionism and

ethical reductionism. Scientific reductionism is the belief that obtaining knowledge is an additive process. The building blocks of this process are specific facts or observations that are localized in time and space. Scientific theories consist in generalizations of laws that aggregate data. Critics argue that this approach to knowledge can never capture the systematic interrelationships of natural and social phenomena and hence will tend to overlook important environmental and social consequences. Spokesmen for the status quo often attempt to meet these criticisms by arguing that the critics' claims are not adequately supported by data. A vicious circle of claim and counterclaim ensues. Scientific reduction is also associated with the philosophical view that science is value free. The claim is asserted in two distinct senses. One is that the process of conducting research and establishing facts through experiment is not influenced by values. The second is that data and theoretical generalizations produced scientifically do not, in themselves, entail value judgments. In application, the alleged value-free nature of science functions very much like an ethical norm, instructing scientists to avoid overt expressions of value judgments in their scientific practice. It is in such applications that scientific reductionism has tended to stifle research, teaching, and public discussion of agricultural ethics.

Ethical reductionism (sometimes called methodological individualism) is the belief that all ethical significance derives from impact on or action of individuals. Costs, benefits, and rights violations alike are, for the reductionist, significant only when they affect individuals, rather than groups or, more abstractly, culture as a whole. Critics argue that changes in farm structure can produce broad cultural patterns that transform the values and world view of future generations. These changing world views may lead future individuals to evaluate farm structure very differently. The ethical individualist does not find the change significant, precisely because individuals living in the future culture are unlikely to perceive themselves as victims. From the reductionist perspective, if no one complains, nothing is wrong. Ethical reductionism is influential because many rural social scientists assume that value is a function of individual preferences. One of the most effective criticisms (unrelated to agriculture) is Aldous Huxley's novel Brave New World, in which citizens of the future are totally content with lives in which they have been genetically, chemically, and behaviorally conditioned to take pleasure in circumstances that present generations would find totally devoid of meaning and morally intolerable.

Scientific reductionism is relevant to ethical analysis of changes in farm structure because some critics believe that changes in farm structure that produce broad-scale environmental, social, and cultural changes are not amenable to analysis and identification by the methods of reductionist science. If choices or policies cannot be justified scientifically, the reductionist concludes that they cannot be justified at all. Ethical reductionism is relevant because, to the extent that these changes affect culture and the transmission of values from one generation to another, it may be difficult to identify harms or rights violations that apply to specific individuals. This theme in the criticism of farm structure overlaps with the next area – conduct and professional ethics.

Conduct and Professional Ethics

The third area of concentration in agricultural ethics has to do with conduct. Agricultural producers and those employed in agribusiness should adhere to standards of professional conduct, and the standards of conduct for agricultural research form a related category. Critics and representatives of the agricultural establishment alike have raised concern over the conduct of those involved in pesticide sales and in certifying the safety and efficacy of input chemicals and agricultural products. Professional conduct is, perhaps, the most obvious area of relevance for agricultural ethics and one where violations of legal and ethical norms can stir significant public attention. Philosophical questions arise in determining the precise role responsibilities of agricultural professionals, but in general, these ethical issues are far less contentious than those that arise in the first two categories. Although the enforcement of norms for good professional conduct can be a difficult practical problem, there is often a broad consensus of opinion even among practitioners on what the norms are.

The writings of Wendell Berry and his followers provide one exception to the generally noncontroversial nature of issues involving ethical conduct. Berry has argued that changes in farming practice and rural communities have produced a situation in which all persons are less able to engage in virtuous conduct. Specialization in food production and distribution has, in Berry's view, fractured the integrity of family-based production and consumption and has made it difficult to perceive social responsibilities to family members and to others in the community. Similarly, this specialization has made it difficult to perceive human dependency on nature and on natural cycles for restoring the environment and replenishing the resource base. Berry thus argues that industrialized agriculture necessitates unethical conduct, not only on part of agricultural producers but also on the part of society at large. Berry's concerns with personal conduct thus overlap with criticism of reductionism discussed above.

Berry's sweeping claims aside, the most serious problems arise in constructing procedures for enforcing what would commonly be regarded as acceptable norms for professional conduct. Farmers may have incentives to abuse chemicals, to adulterate products (spraying water into a grain truck to increase weight is a well-known abuse), or to cheat on Federal programs. Similarly, agribusiness firms producing inputs may have incentives to misrepresent the safety and effectiveness of their products, and food-processing firms may have incentives to pass contaminated or adulterated products on to consumers. Finally, public officials, including research scientists, may have incentives to favor special interests, including industry and producers, over the public good. Philosophical questions arise in how government should regulate such activities and when penalties should be applied for noncompliance. This area of agricultural ethics becomes closely involved in agricultural law.

Research Ethics in Agricultural Science

The conduct and professional ethics of agricultural scientists deserve special attention. Whether basic or engaged, science is

an activity dedicated to the production of knowledge. Scientists have long recognized that the success of this enterprise depends on strict adherence to the norms of honesty in reporting results and openness in being willing to consider alternative hypotheses. First-order issues in research ethics stress the importance of these norms to the research enterprise and decry the occurrence of fraud, deceit, and coercion in science. These norms can be described as an element of professional ethics for the scientist. The doctrine of academic freedom was advanced in the nineteenth century to protect the openness of scientific inquiry and to protect scientists from reprisal when they reported unpopular results. Historically, scientific organizations have relied on the process of socialization to enforce norms of honesty. During recent years, however, it has become clear that scientists can advance their careers, as well as commercial products, through fraud and deceit, and new concerns have been raised about the integrity of the scientific community.

Recent work in the philosophy of science by Steve Fuller and in the sociology of science by Bruno Latour has established the basis for understanding second-order issues in research ethics. These authors have shown how scientists are taught to believe that science is founded on value-free objective procedures, whereas ethical norms are based on emotion or mere opinion. Belief in the value-free nature of science is often expressed as scientific and ethical reductionism, as discussed above. Belief in the value-free nature (e.g., objectivity) of science does not strictly entail that ethical questions about the choice of a scientific research project, or about the unintended consequences of a scientific finding, are inimical to the methods and practice of science. Nevertheless, practices in many agricultural research organizations discourage deliberation of ethical issues as unscientific. Although these beliefs represent value judgments themselves, they have allowed scientists to project a public image of being neutral parties, committed only to the facts, and unmotivated by value judgments or norms.

When the belief that science should always produce more knowledge is combined with a belief that applying ethical standards to research choice is inimical to science, scientists and scientific organizations may become committed to a goal of always increasing knowledge but at the same time rejecting the legitimacy of other interests that may oppose the creation of new knowledge (or may feel that resources are better invested in other goals). Scientists who adopt this posture pursue funding and freedom to conduct research but refuse to participate in debate over the goals or value of research on the grounds that doing so will comprise objectivity. In this situation, scientists are an interest group whose interests depend on being thought to have no interests. The situation creates incentives for duplicity and self-deception within the scientific enterprise and may ultimately erode scientists' commitment to the norms of honesty and openness. The alternative is to reject either the norm of advancing knowledge or the belief that science is value free. Either way, scientists have a responsibility to review the value of their research programs and to at least consider the significance of unintended consequences. The conclusion is that the second-order ethical deliberation should be accepted as an intrinsic element of scientific practice.

Animal Well-Being

The legal and ethical protection of animals has a long standing in the United States. Anticruelty statutes were enacted in some colonies before the Revolutionary War. More recently, animal protectionists have noted concern for the well-being of farm animals in confinement settings, especially since the publication of Ruth Harrison's Animal Machines in 1966. However, the principal focus of the recent animal rights movement has been to oppose the use of animals in product testing and biomedical research. The biomedical debate has become quite acrimonious, with some parties on both sides taking extreme positions. Few in ethics would deny that caregivers have ethical responsibilities to assure well-being of farm and food animals.

Farmers and ranchers have traditionally been thought to be especially respectful of the well-being of food and farm animals. They have been thought to possess personal moral concern for animals. Also, animal health and well-being have been thought to correspond closely to a producer's interest in efficiency and marketability of animal products. The correlation between producer and animal interests fails to obtain when any one of three conditions obtains. First, some products, such as *foie gras* or pale veal, may require production methods contrary to animal well-being. Second, some elements of animal well-being may be realizable only under ideal conditions seldom realized in either wild or domesticated settings. Third, with large operations or high stocking rates, the management costs of attending to the needs of a few individual animals will not always be matched by returns based on average or aggregated sales of animal products. Animal protection organizations have criticized agricultural producers on each of these three points. The political rhetoric of the animal experimentation debate influences criticisms of agriculture, and ambiguous terminology presents a barrier to any clear presentation of ethical issues. Multiple uses for the terms animal welfare and animal rights are especially confusing. For some, the term 'animal rights' implies an extreme reformist position, whereas 'animal welfare' is taken to imply an attitude favoring moderate or no reform in animal agriculture. Popular use suggests that those who express support for animal rights merely feel that individual animals' interests deserve consideration and do not propose radical change in animal agriculture. More formal uses of these terms have been introduced into the literature by two influential philosophers, Peter Singer and Tom Regan.

Peter Singer advocates an animal welfare philosophy in a series of articles and in his book Animal Liberation. Singer is a utilitarian philosopher who believes that the morality of an action is to be evaluated by assessing its consequences. The key to the animal welfare philosophy is the belief that comparable interests deserve equal consideration without regard to species. This means that comparable experience of physical pain, for example, would be given equal consideration without regard to whether the pain is experienced by a pig, monkey, or a human being. Singer explicitly notes that many interests do not admit of meaningful cross-species comparisons and that the complex cognitive interests of human beings establish bases for evaluating consequences to humans in a manner that is unparalleled for other species. Hence, Singer's view admits of many opportunities in principle where human interests are

favored over animals' and even where animal pain or suffering may be justified by compensating benefits to humans. However, Singer is also of the opinion that animals in confinement settings suffer to a degree that makes it impossible to justify human consumption of food animals. Hence, he is commonly associated with the so-called animal rights group advocating radical change.

Tom Regan has made numerous public appearances on behalf of animal interests, especially since the publication of his book The Case for Animal Rights in 1983. Regan advocates an animal rights philosophy that is opposed to the animal welfare philosophy of Singer. In summary, Regan's view states that Singer's utilitarian position does not provide adequate reason for protecting the interests of individual animals. Aggregation of costs and benefits to human and nonhuman animals leaves open the possibility that significant harms to a few individual animals can be compensated by relatively insignificant benefits to a large number of human beings. This argument has been especially relevant to the cases of product testing and scientific research. According to Regan, animals are 'subjects of a life.' Accordingly, humans must respect their interests. Although Regan's view would allow priority to comparable human interests (e.g., one might sacrifice animal lives to save human lives), his animal rights philosophy prohibits the aggregation of relatively low-level interests (such as gustatory pleasure) to compensate for harms of an ethically fundamental sort.

Although the writings of Singer and Regan represent the philosophical distinction between animal welfare and animal rights, both have advocated vegetarianism. For Singer, vegetarianism is a specific response to the use of confinement systems and high stocking rates. For Regan, vegetarianism is a general moral responsibility that would apply at all times and places. As both Singer and Regan are sharply critical of animal agriculture, the more moderate views of Bernard Rollin have had more influence within animal science and veterinary medicine. Rollin has written several influential works, such as his 1987 book The Unheeded Cry, but a paper entitled 'Animal welfare, animal rights and agriculture' provides a particularly concise statement of his views. For Rollin, the idea of animal rights represents the consensus judgment of society that the interests of individual animals matter and that producers may be required to sacrifice financial gains in order to assure that vital interests are met. Rollin thinks that this idea is generally consistent with traditional notions of animal husbandry, but the emphasis on narrow scientific or economic measures of productivity and animal health have caused erosion of moral concern for food animals. Rollin urges animal rights as a philosophy that is, in effect, a return to more humane and responsive practices of traditional husbandry.

Agricultural Biotechnology

The rapid growth of recombinant deoxyribonucleic acid (DNA) transfer techniques and their application to agricultural science have created a situation in which agricultural biotechnologies present excellent case studies for many of the ethical issues discussed above. Unintended consequences of agricultural biotechnology have stimulated the most acrimonious debate. In the early 1980s, Jeremy Rifkin's Foundation for Economic Trends filed lawsuits designed to ensure that those undertaking research and development of agriculture biotechnology assume responsibility for all social and environmental consequences. The first round of debate focused on ice-nucleating bacteria that could provide crop protection against freezing temperatures as low as 30 F (-1 °C). Rifkin delayed experiments with these bacteria by raising questions about whether scientists had undertaken adequate review of potential environmental consequences.

The second round of debate had focused on recombinant bovine somatotropin (BST), a genetically engineered version of the hormone that can be used to stimulate milk production in dairy cows. The unintended consequences that raised concern with BST stressed social impact on the structure of the US dairy industry. Economic analysis predicted that the technology would accelerate a shift from small to large dairies and from the northeast to the south and southwest as principal production regions. Concern over the impact on the health of dairy cows has been raised, largely associated with mastitis problems associated with the increased volume of milk production. Finally, consumer groups expressed reluctance to accept milk produced using recombinant BST, despite scientific evidence documenting safety and quality.

In addition to these problems associated with unwanted consequences, recombinant techniques have been associated with ethical questions about property rights and about the religious and metaphysical implications of biotechnology. Property rights issues concern the question of whether newly discovered or assembled segments of genetic code qualify as patentable material or material that can be owned. The issues have been most hotly debated for animal patents. On the side of animal patents is the incentive effect of property rights for potential producers of recombinant technologies. Against animal patents are the claims that genetic sequences are 'nature's handiwork' and that biotechnologies should be regarded as scientific discoveries (which are traditionally not patentable) rather than as inventions. Religious and metaphysical considerations enter the discussion of property rights when people express the view that life forms should not be owned or, perhaps, manipulated. In this regard, the emergence of biotechnology has apparently brought longstanding practices of genetic manipulation and breeding into the public consciousness for the first time.

Biotechnology is religiously significant because for some people, at least, the ability to move genetic material from one animal to another raises questions about the ethical significance of species boundaries. These questions are of two sorts. First, theologies that propose a difference in kind between human and nonhuman animals are challenged by the new molecular biology. Second, some religious views interpret the existing distribution of species as God's handiwork and interpret genetic modification as a violation of absolute constraints on human action. Religiously based concerns often enter debates indirectly, being expressed along with secular ethical concerns about property rights or unwanted consequences. The US tradition of separating church and state may make religiously based arguments seem less legitimate in the public policy context.

Glossary

Agribusiness Refers to farm input supply firms, food processing firms, fiber manufacturing firms, and other firms in the nation's food and fiber system other than crop and livestock producers.
Credit scoring Approach used by lenders to quantitatively evaluate the credit worthiness of a borrower.
Farm Credit System System of federally chartered, privately owned banks, and associations that lend primarily to agricultural producers and their cooperatives.
Farm Service Agency Governmental agency involved in direct lending and loan guarantees to creditworthy borrowers that may have a difficult time obtaining financing from commercial sources.
Financial intermediaries Entities that obtain loanable funds from savers in the economy and then lend these funds to borrowers.
Food and fiber industry Network of input supply firms, crop and livestock producers, food processing firms, fiber manufacturing firms, and related distribution firms associated with the supply of food and fiber products to final demand.
Macroeconomic policy Typically refers to the monetary actions taken by the Federal Reserve System, the government spending authorized by the US Congress, and the taxation policies approved by the US Congress and implemented by the Internal Revenue Service.
Net present value Discounted sum of projected net cash flows for a potential investment.
Risk efficient frontier Set of asset that offers the maximum possible expected returns for a given level of risk.
Risk premium Difference between a decision maker's expected risky return and value the decision maker would accept if all risks were removed.
Vertical integration Coordination and integration of successive stages in production, processing, and distribution.

Introduction

The field of agricultural finance encompasses a broad range of interest ranging from 'micro' issues associated with firm-level investment and financing decisions made by crop and livestock producers as well as agribusiness firms to 'macro' issues associated with the effects that macroeconomic policy, farm commodity policy, resource policy, and international trade policy have on the financial structure and performance of the nation's food and fiber system.

Microagricultural Finance

Topics in microagricultural finance include concepts of investment and financing decisions under both certainty and uncertainty, including the methods used to evaluate investment projects and alternative approaches to acquiring these resources.

Overview of Financial Management

The concepts of financial management in agriculture involve the acquisition and utilization of financial resources by crop and livestock producers and by agriculturally related businesses. Emphasis in this section is placed on the introductory concepts of theory of investment and financing decisions, the evaluation of new investments, resource acquisition in agriculture, financial analysis in agriculture, and the financial intermediaries involved in delivering debt capital to agriculture. Major microissues related to agricultural finance are also presented. These issues and concepts are linked throughout the entire food and fiber system: from input supply firms and financial intermediaries to crop and livestock producers, and onto food and fiber manufacturers and distributors.

Theory of Investment and Financing Decisions

The fundamental concepts of finance theory apply similarly to farms and ranches as well as other firms in the economy. Crop and livestock producers typically have relatively little market power, often being price takers in both input and product markets. Agribusinesses like input manufacturers have more market power and often participate in thinner, less-liquid markets.

Concepts of investment and financing decisions under certainty

The major components of financial theory include a decision maker's utility function, productive investment alternatives, and financial markets. A simple model with no taxes, no transaction costs, and no uncertainty of investment decisions is used to outline the theoretical framework. Decisions are made in a one-period context. The decision maker is endowed with income at the beginning of the period and at the end of the period. At the beginning of the period the individual determines how much to consume (C_0) and how much to invest to provide for end-of-period consumption (C_1). All individuals prefer more consumption to less (marginal utility of

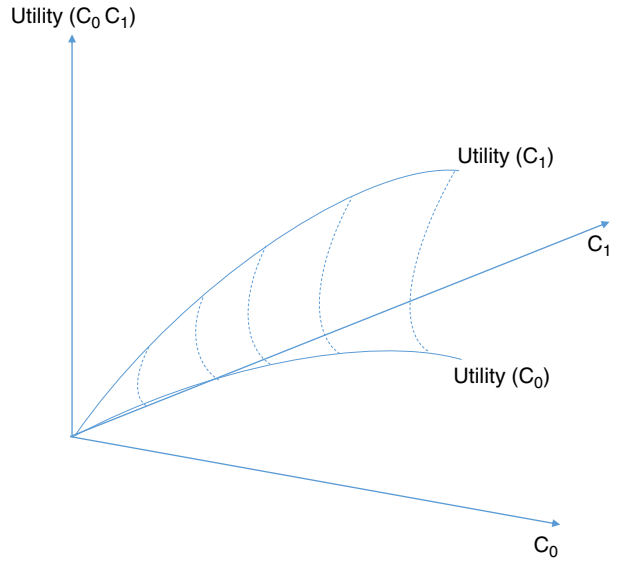

Figure 1 Utility functions and indifference curves. C_0 is beginning of period consumption, C_1 is end of period consumption, the dashed contour lines represent the indifference between beginning and end of year consumption.

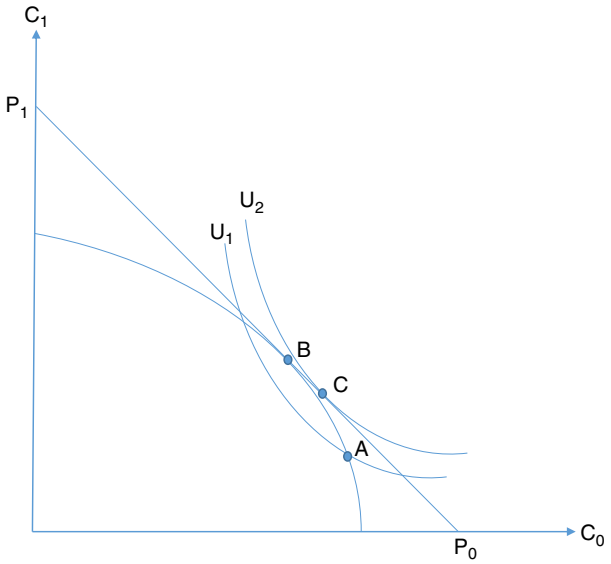

Figure 2 Optimal investment and financing decisions. The production possibility set is represented by P_0P_1 and the set of indifference curves by U_1 and U_2.

consumption is always positive) and hence the marginal utility of consumption is decreasing. Utility curves for beginning-of-period and end-of-period consumption are shown in Figure 1. Each individual may have different utility curves. The dashed contour lines indicate trade-offs between beginning-of-period consumption and end-of-period consumption. Utility is equal at points along these contour lines, and the lines thus are referred to as indifference curves. The slope of a line tangent to an indifference curve measures the rate of trade-off between C_0 and C_1 and is referred to as the marginal rate of substitution between beginning-of-period consumption and end-of-period consumption. The slope of this line can be represented as $-(1+r)$, where r is the individual's subjective rate of time preference.

Assume individual decision makers have opportunities to invest in productive assets that allow units not consumed at the beginning of the period to be augmented to more than one unit of future consumption. In the absence of financial markets, an individual decision maker will invest in all productive opportunities that have rates of return higher than the decision maker's subjective rate of time preference (r).

To complete the model, assume that financial markets exist and thus there is an opportunity to lend and borrow unlimited amounts at a market-determined rate of interest (i). These borrowing and lending activities allow the individual decision maker to reallocate consumption between the beginning and end of the period to attain higher levels of utility and thus improve economic well-being. The presence of financial markets allows the individual decision maker to invest in all productive assets that have rates of return that equal or exceed the market rate of interest (i) instead of the subjective rate of time preference.

These concepts are illustrated in Figure 2. The production possibility set is represented by P_0P_1 and the set of indifference curves by U_1 and U_2. Given that interest rates are positive, all funds lent at the beginning of the period will receive interest plus principal at the end of the period. The future value of one unit lent at the beginning of the period is increased by a factor of 1 plus the market-determined rate of interest (i). Thus, the slope of the capital market line is $-(1+i)$.

Suppose the initial endowment is point A. The individual decision maker may move along the capital market line or production possibilities set to achieve the highest possible utility. In this example, the higher return is achieved by moving up the production possibilities set to point B where the rate of return on investments is equal to the market rate of interest, a tangency with the subjective rate of time preference (U_2) is achieved at point C. This tangency is at a higher level of utility than that achieved without financing opportunities.

Thus, the process can be depicted as a two-stage process. First, the individual decision maker invests in all production opportunities that have returns, which equal or exceed the market rate of interest. Second, the individual decision maker borrows or lends in the financial market until the market rate of interest is equal to the decision maker's subjective rate of time preference. The first step does not use the decision maker's utility function and thus, under certainty conditions, the investment condition (stage 1) is considered separate from the financing condition (stage 2). This condition is known as the Fisher Separation theorem.

Concepts of investment and financing decisions under uncertainty

Crop and livestock producers are inherently faced with risk. Commodity price fluctuations, weather variability, spoilage, disease, and changes in government policies interject considerable risk into their decision-making process.

The three theoretical concepts essential to understand financial models under uncertainty include concave utility functions, certainty equivalents, and risk premiums. The marginal

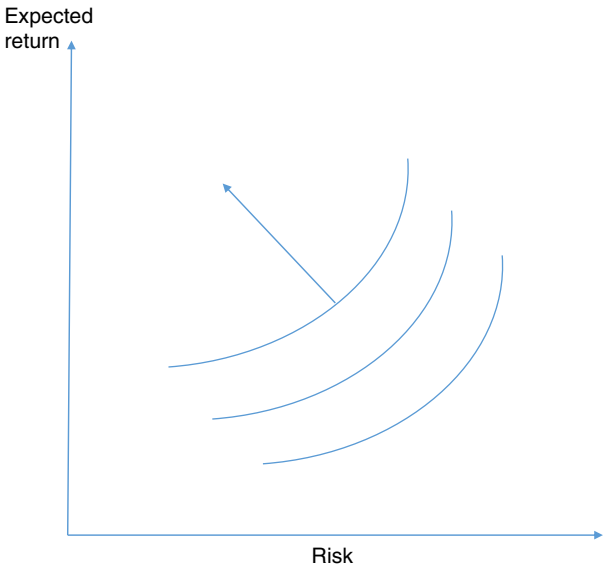

Figure 3 Indifference curves and attitudes toward risk. Indifference curves between risk and return for risk adverse investors. Preference is upwards and to the left.

utility of profit declines for concave utility functions. Crop and livestock producers with concave utility functions are considered risk averse. Risk-averse decision makers prefer a certain investment to one with an equal but uncertain return. A risk-averse decision maker is willing to pay a price for a certain investment that yields the same utility as the expected utility of the risky investment. The completely certain price is considered the certainty equivalent. The difference between the expected value and the certainty equivalent value is the risk premium. The risk premium is the decision maker's required compensation for accepting risky investments.

A risk-averse decision maker's preference structure between risk and return can be represented by indifference curve analysis. Figure 3 shows indifference curves for risk-averse decision makers. The direction of preference is represented by an arrow (up and to the left). The slope of the indifference curves indicates the marginal rate of substitution between risk and return. In this case, the marginal rate of substitution is the amount of expected return the decision maker requires for an additional unit of risk. Different decision makers will have different degrees of risk aversion and thus will have different marginal rates of substitution.

Investment decision techniques under certainty

In the previous sections a simple one-period model is discussed. These models are extended to incorporate multiperiod investment decisions and refined to evaluate alternative projects. The methods are referred to as capital budgeting techniques. These techniques are used to aid investment decisions for all types of agribusiness firms. Refinancing of debt and buy versus lease decisions are also analyzed using these techniques. The techniques can be used to select among independent projects or rank mutually exclusive projects based on specific budget constraints. In general, there are five capital budgeting techniques used to evaluate investment decisions. These include the following: (1) the payback method, (2) the accounting rate of return method, (3) the net present value method, (4) the internal rate of return method, and (5) the modified internal rate of return method.

The payback and accounting rate of return methods do not account for time value of money and thus limit their overall usefulness. The payback period is calculated as the number of years it takes to recover the initial cash outlay. The accounting rate of return is the average after-tax profits divided by the initial outlay.

The three other methods each account for the time value of money. The net present value of a project is calculated as the sum of all discounted cash flows of the project. Each cash flow is discounted by factors that convert each cash flow into a net present value. The factors are based on the decision maker's opportunity cost of capital. The internal rate of return of a project is the rate that equates the present value of all inflows and outflows. However, the method assumes that all cash flows can be reinvested at the internal rate of return. The modified internal rate of return is calculated by first finding the net present values of all cash outflows using the decision maker's opportunity cost of capital. Second, the future value of all cash inflows are estimated also using the decision maker's opportunity cost of capital. The modified internal rate of return is the discount rate that equates the present value of the cash outflows with the future values of cash inflows.

The net present value and modified internal rate of return are the preferred methods. Mutually exclusive projects of similar size are ranked the same with each method. However, when size differences among the projects occur, the net present value method provides a more consistent indicator of how an individual project will affect the overall value of a firm.

Adjustment for risk in decision making

Each of the five methods discussed in the previous section assumes certainty of future cash flows. However, considerable uncertainty is present among agribusiness firms. Four general methods have been used to account for risk in the investment decision framework. These include the following: (1) the maximin decision criterion, (2) the coefficient of variation criterion, (3) the expected present value criterion with adjusted discount rates, and (4) the certainty equivalent criterion. Each of the methods have drawbacks with the choice of method depending on the frequency the decision maker is confronted by similar investment decisions, the magnitude of the risk involved, and the decision maker's aversion to risk.

The maximin decision criterion uses the maximum (or the largest) of the minimum (or the smallest) outcomes associated with a decision alternative. This criterion simply selects the decision alternative with the best of the worst outcomes. The method does not account for the probability of any of the outcomes. The coefficient of variation is the ratio of the standard deviation of possible outcomes divided by the expected present value. For the coefficient of variation criterion, the decision maker chooses the decision alternative that has the lowest, nonnegative coefficient of variation. This method does not account for differing degrees of risk aversion.

Another commonly used method is to adjust the discount rate for decision alternatives with different levels of risk. A problem with this method is the data required to estimate the

adjusted discount rate. The certainty equivalent criterion involves selecting the decision alternative with the highest certainty equivalent. This criterion incorporates the risk aversion of the decision maker. However, the values that are used to estimate a decision maker's utility function and certainty equivalent are subject and difficult to estimate quantitatively.

Resource Acquisition in Agriculture

The financial barriers to enter production agriculture have increased. Inflation, technological change, and increases in farm size have been the primary causes of the increased capital requirements. The combination of increasing capital requirements and low profit margins restricts crop and livestock producers in their capacity to acquire control of the land, machinery, livestock, and other resources necessary to compete. The increased capital requirements also limit growth. Crop and livestock producers are evaluating and using alternative methods of resource control and management.

Sources of funds used to acquire control of resources can be broadly classified as debt and equity capital. The degree to which that debt capital is used by a producer is a key issue. Tax deductibility and cost usually favor the use of debt capital over equity capital, whereas administrative and bankruptcy costs increase as the proportion of debt capital increases. Thus, theoretically each decision made may have an optimal equilibrium combination of debt and equity.

Equity capital

The primary source of equity capital in production agriculture is through retained earnings or surplus profits kept in the business. Other common sources of equity capital have resulted from gift and inheritances from previous generations and pooling of equity capital through partnerships or corporations.

There are two types of partnerships common in agriculture: general partnerships and limited partnerships. With general partnerships, each partner is explicitly involved in both ownership and management. Furthermore, each partner has unlimited liability for obligations incurred by the business and the liabilities incurred by other partners. Limited partnerships are comprised of limited and general partners. The liability of the limited partners is restricted to the investment in the business.

The corporation is a legal entity held as share or claims on the net worth and profit stream of the business. Although partnerships and sole proprietors dissolve on death, corporations permit continuity over generations. Two types of corporations are important in agriculture: Subchapter S and Subchapter C. A Subchapter S corporation is limited to 35 stockholders and taxed as a partnership. With the Subchapter S corporation, all profits are allocated to the stockholders for income tax purposes. A Subchapter C corporate stockholder must pay taxes only on the cash dividends received and thus this entity may offer some income tax incentives for high-tax-bracket stockholders.

Many corporations and partnerships are created for the purpose of pooling family equity capital. However, public and private placements of equity shares in production agriculture are becoming more common in agriculture. An example is life insurance companies that are becoming more active in acquiring equity shares in agricultural operations as well as direct investment in agricultural assets as methods to diversify pension funds.

Leasing

An arrangement commonly used in agriculture is the farm lease. The lease basically transfers capital from the lessor to the lessee for an agreed period of time. Leasing is a common method for producers to control farmland. Share leases and cash leases are common with real estate leases. With crop share and livestock share leases, the lessor and lessee share in the costs and production, whereas the cash lease is simply an agreed cash price paid for the rental of the land.

Machinery and equipment leasing is also common in agriculture. In agriculture, operating and capital leases are used to acquire control of machinery and equipment. Operating leases are short-term contracts ranging from a few hours to a year. Custom hiring is a common operating lease arrangement. Custom hiring involves the owner furnishing the machine, operating expenses, and labor. Capital leases are a longer term arrangement. The financial obligations of capital leases are quite similar to debt arrangements.

Contract production

Agriculture has witnessed strong trends toward increasing specialization and coordination at the various stages of the production cycle. The coordination may be with successive stages in production and distribution (vertical) or between two or more units of production within the same economic stage (horizontal). Vertical integration of input suppliers, processors, and distributors is becoming more common in agriculture. An increasing proportion of assets used in the farming sector is being supplied or financed by input suppliers, processors, and distributors. Vertical integration of vegetable and fruit industries has been in existence for a long time. Livestock industries, such as poultry and hogs, are also becoming more vertically coordinated. A producer may be able to shift price and yield uncertainties to the contracting firm with vertical coordination. However, future contractual arrangements create additional uncertainties.

Debt capital

Debt capital are funds acquired from financial intermediaries. Costs include interest costs, fees, and closing costs. Interest costs are fully tax deductible and thus typically carry a lower cost than equity capital. Debt capital is typically distinguished between operating debt and term debt. Operating debt is used to finance the purchase of operating inputs, whereas term debt is often used to finance depreciable assets and farm real estate. Operating debt is typically repaid during the production cycle, whereas term debt is paid over several years.

Financial Analysis of Agricultural Producers

The accounting practices followed by many crop and livestock producers have traditionally been both informal and simplistic. However, the increasing use of debt capital and the

formation of more complex organizational structures have increased the need of standardization of financial records for crop and livestock producers.

Accounting practices

In conjunction with the 1987 Agricultural Credit Act, a presidentially appointed commission on agricultural finance emphasized the need for greater standardization of financial reports and analysis of the farm industry. As a result, the Agricultural Division of the American Bankers Association formed a task force of representatives from lending institutions, academic institutions, regulatory agencies, computer software firms, the farm management consulting industry, and the accounting industry. The Farm Financial Standards Task Force, renamed to Farm Financial Standards Council (FFSC), provided guidelines regarding the reporting of financial information for farm and ranch businesses.

The four financial statements recommended by the FFSC include the following: (1) the balance sheet, (2) the income statement, (3) the statement of cash flows, and (4) the statement of owner equity. These four statements are linked to provide a business (assets) and the levels of debt and equity used to acquire the assets. The income statement is a summary of the revenue and expenditures of the business over a specified period of time. The statement of cash flows is a detailed summary of the cash inflows and outflows over a specified period of time. The cash inflows and outflows are separated according to operating, financing, and investment activities of the firm. The statement of owner equity reconciles the change of equity from one period to the next.

Each of these statements may be prepared on a historical basis or a pro forma (projected) basis. These financial statements organized the data needed to analyze the risk and performance of the business. The primary areas of analysis include solvency, profitability, liquidity, repayment capacity, and financial efficiency. Solvency measures the level of debt relative to the equity capital or the overall capital of a business. Profitability is the ability of the firm to generate earnings, whereas liquidity relates to the firm's capacity to generate cash to meet financial commitments without loss of value. Repayment capacity measures related cash generated by the operation to cash obligations of the firm. Financial efficiency measures refer to the utilization of assets within the business. Other financial efficiency measures relate operating and financing expenses to total production.

Credit scoring and risk rating systems

Financial statements and financial ratios measure the degree of financial risk faced by a crop or livestock producer. Crop and livestock producers use the measures to monitor financial strength and future growth capabilities, whereas financial intermediaries use the measures to determine credit worthiness of an operation.

More formal risk rating systems of credit evaluation are currently being implemented by agricultural lenders. The risk rating systems are designed to measure (1) the borrower's potential default on a loan or probability of default and (2) the magnitude of potential loss, given that a default has occurred or loss given default. The goal of the ratings is to array borrowers and loans from the highest credit default risk to the lowest.

Risk rating models have been developed through lender's experiences as well as statistical methods. The lender experience models are formulated by lenders based on historical observations of variables that are related to overall loan performance. Statistical development of risk rating models involves the mathematical representation of a group of subjective and objective independent variables into an equation that determines the credit worthiness of a business. The objective variables often include collateral value, financial ratios, production efficiency measures, and trend values of financial measures. Management ability is a common subjective measure included in risk rating models. The applications of risk rating models include determination of credit acceptance, loan pricing based on riskiness of the loan, establishment of loan loss provisions, and loan portfolio monitoring. The dependence on the model results varies among lenders. In some cases, model results are used as the sole determinant in the decision process, whereas other lenders use the results in conjunction with other criteria.

The statistical approaches used to determine the variables and their respective coefficients include linear regression, discriminant analysis, and logistic regression. The independent variables include various financial, economic, and subjective variables, whereas the dependent variable is a measure of historical loan performance. In general, results indicate that the independent variables selected and their respective coefficients differ substantially across studies and are very sensitive to the data sample.

Providers of Debt Capital

The major sources of debt capital to agriculture include: (1) commercial banks, (2) the Farm Credit System, (3) life insurance companies, (4) Farm Service Agency (FSA), (5) farm-related trade and agribusinesses, (6) individuals, and (7) Farmer Mac. Each of these sources play a vital role in providing debt capital to agriculture. However, sources of funds, regulatory constraints, and individual risks faced by each are different.

The forecasted amount of farm debt outstanding at the end of 2013 is US$308.3 billion. On 31 December 2012, commercial banks held 39.6% of all farm loans with the Farm Credit System holding 40.7%. This is a significant shift in market shares from 1982 when commercial banks held 22.2% and the Farm Credit System held 34.0%. A large reason for the shift in market shares has been the increased emphasis of commercial banks on farm real estate lending. The market share of farm real estate debt by commercial banks has increased from 7% in 1982 to 34% by year-end 2012. The market share for the Farm Credit System increased from 43% to 46.1% over the same time period.

Currently, issues involving providers of debt capital to agriculture include the following: (1) the role and performance of the Farm Credit System, (2) consolidation activities of commercial banks, (3) the increased competitive position of nontraditional lenders, (4) increased regulatory environment resulting from the financial crisis, and (5) government lending.

Role and performance of the farm credit system

Institutions in the Farm Credit System are federally chartered and privately owned. One objective of the charter is to improve the income and well-being of crop and livestock producers by furnishing competitively priced credit and related services to creditworthy borrowers through all economic conditions.

The primary sources of funds for the Farm Credit System district banks are obtained through the sale of system-wide securities in the national financial markets. The Federal Farm Credit Bank Funding Corporation is responsible for selling the securities. The securities are treated as Governmental Agency Securities and trade at 20–50 basis points above US Treasury securities. Equity capital of the various cooperatively controlled banks and associations is obtained by sale of stock to borrowers and through retained earnings. The banks are regulated by the Farm Credit Administration.

During the early 1980s, the Farm Credit System experienced severe financial problems. The system's capital and surplus declined to more than US$6.1 billion in 1985 and 1986. The problem involved loan losses resulting from producers' financial problems as well as lowering net interest margins. The Farm Credit System held a large volume of long-term securities at high interest rates whereas current market rates on loans were low. As a result, in December of 1987, the US Congress passed the Agricultural Credit Act of 1987. The major provisions included restructuring options of the Farm Credit System, federal financial assistance, greater flexibility in capitalizing the system, and creation of an insurance fund.

Currently, the Farm Credit System institutions have restored the soundness of their operations: restructuring of the System's banks and lending associations is continuing as these institutions seek great efficiency and risk-bearing capacity in their lending operations. On 1 January 1988, there were 12 districts with a total of 377 associations. On 1 July 2013, there were 4 districts and 82 associations. The impact the corporate restructuring of the Farm Credit System has on the delivery of debt capital to farm and ranch borrowers has also received considerable interest among policy makers, academicians, credit institutions, and borrowers themselves.

Consolidation activities of commercial banks

Considerable consolidation has occurred within the commercial banking industry. There were 14 507 commercial banks in 1984. By year-end 2012, there were 6112. Most of the reductions were a result of unassisted mergers. The bank merger and acquisition activity was higher than any other industry over this time period. As a result of changes in federal and state legislation, interstate acquisitions by bank-holding companies have been a large part of this acquisition activity. Since states liberalized geographical expansion regulations, interstate banking has increased.

The growth of mergers and acquisitions in the banking industry has been accompanied by a multitude of theories and philosophies debating the rationality and public benefits of this expansion activity. Opponents of bank combinations suggest that undue concentration may inhibit competitive forces and thus increase monopoly elements in the economy. In addition, opponents in rural areas argue that acquisitions often result in locally disinterested intermediation activities and decisions. Some of the activities suggested by adversaries of bank expansion include siphoning deposits out of rural areas, warehousing out-of-market loans at the subsidiaries, and allocating nonproportional operating expenses to subsidiaries. These adverse activities could result in higher credit costs to borrowers or reduced credit availability to agriculture and other small businesses in local communities. Advocates of bank expansion suggest that combinations will benefit society by reducing inefficiencies in the banking system through resource reallocation. The potential for geographical and produce diversification also exists. In addition, local community services may be enhanced by additional services available through larger institutions.

The consequences of the heightened consolidation of the banking industry are essential components in the agricultural economy as well as the national economy. Commercial banks held over US$118 billion of agricultural debt outstanding as of end of year 2012. As a result, estimations of inefficiencies within the banking industry and the evaluation of the changes in competitive forces due to structural shifts within the banking industry are research areas receiving considerable attention among researchers in agricultural finance.

Increased competitive position of nontraditional lenders

Another current issue in agricultural finance related to the emergence of other nontraditional lenders is the increased competitive position of nontraditional lenders. Vertical integration is becoming more prevalent in some areas of production agriculture, especially in the livestock sector. The vertically integrated firms are typically much larger and more complex than the traditional family operated businesses. Furthermore, credit demands for these firms are also different. In many cases, the small-community bank and the Farm Credit System have been unable to meet the credit demands of these firms. Therefore, these firms have accessed nontraditional sources of capital through large commercial banks or investment banking firms.

Other nontraditional lending sources are also becoming more competitive. These nontraditional lenders include input supply firms and farm implement dealers. Loans from these firms are typically derived from the purchase of a farm input or product. However, these firms are also expanding into operating lines of credit. The facilitation of sales, convenience to borrowers, and profitability are primary motivations for these firms to offer credit. Compared with the highly regulated banking industry and Farm Credit System, these nontraditional firms face few regulatory hurdles. Opponents of these firms often argue that an unfair playing field exists. The evaluation of the competitiveness and viability of these firms to deliver debt capital to crop and livestock producers is an emerging concern in agricultural finance.

Increased regulatory environment resulting from the financial crisis

Most institutions lending to the US agriculture weathered the financial tsunami and the economic recession resulting from the 2007 global financial crisis. Many of the agricultural-related institutions did not participate aggressively in the high-risk housing or commercial real estate markets. As a result, institutions lending to agriculture did not sustain the substantial

liquidity and capital problems faced by many global financial institutions. In general, credit remained available for farmers and ranchers throughout the financial crisis. The profitability of production agriculture through the crisis certainly played a critical role in credit quality and quantity at institutions providing capital to agriculture.

Regulatory costs, including the Dodd–Frank Wall Street Reform and Consumer Protection Act, present challenges for many institutions lending to agriculture and rural America. As a share of total operating costs, these regulatory costs are greater for smaller institutions. Regulators are also placing higher regulatory emphasis on banks with significant concentrations in industry sectors, such as agriculture. The implementation of the Basel III capital requirements also place additional costs on institutions lending to agriculture. The spillover impacts of the Dodd-Frank regulations to the agricultural sector will most likely reduce profit margins at institutions.

Government lending

As an agency of the US Department of Agriculture, the FSA serves as a source of debt capital for rural Americans. The FSA originates loans and guarantees loans to qualified applicants who have experience in farming and ranching, who are the owners or operators of a farm or ranch at the time of borrowing the loan, and whose livelihoods depend on farming or ranching.

Concerns have surfaced regarding government subsidies that have focused increased interest on reducing FSA direct lending and increasing its emphasis on loan guarantees. Loan guarantees transfer the funding and loan administration to private lenders and provide greater flexibility in loan pricing.

Macroagricultural Finance

The second major area of emphasis in agricultural finance reflects an aggregate or 'macro' view of the economic performance and financial structure of the nation's farms and ranches and their relationship to other sectors in the general economy. Information on macroagricultural finance developments is of interest to macroeconomic policy makers, farm commodity policy makers, financial institutions and their regulators, agribusinesses, and rural development specialists.

Sector Economic Accounts

An important foundation to macroagricultural finance has been the development of a system of economic accounts for agriculture. Most economists are familiar with the national income and product accounts maintained by the US Department of Commerce and the flow of funds accounts and national balance sheet maintained by the Federal Reserve System. Many, however, are more likely aware of the role the US Department of Agriculture plays in supplying the sectoral information for agriculture incorporated into these national accounts or the applications agricultural economists make of these sectoral data. The set of economic accounts for agriculture, developed and largely maintained by the US Department of Agriculture, not only provides input to the economy-wide set of accounts but also represents a major source of data to descriptive and quantitative behavioral research in agricultural finance.

Sector income account

The US Department of Agriculture's sector income account dates back to the early 1900s (U.S. Department of Agriculture, 2013). This account has been expanded over the years to provide detailed information on cash receipts from farm marketing of crops and livestock, government payments, and other sources of farm-related income. This account also provides detailed information on farm production expenses, capital consumption, and capital expenditures for durable production inputs like tractors and other farm machinery and equipment, trucks, and farm structures.

Figure 4 shows the historical trends in nominal and real net farm income reported in the sector income account. Nominal net farm income has increased sharply since the turn of the century, whereas the purchasing power of net farm income has increased at a much more modest pace. Along with the rise in net farm income, considerably more year-to-year variability is seen, particularly since the commercialization of the ethanol industry.

If one looks below the sector level, one will find that the growth in biofuels has increased the demand for feed gains used in producing ethanol, which while driving up feed grain prices received by crop producers has driven up feed costs for livestock producers, narrowing/eliminating their profit margins in recent years.

Higher net farm incomes in general, however, have allowed many producers to pare back their leverage positions. The combination of reduced indebtedness and historic low interest rates resulting from extraordinary monetary policy measures employed by Federal Reserve to combat the 2007–09 recession has led to a marked decline in interest expenses relative to farm sector revenue as shown in Figure 5. This trend peaked in 1983 when the combination of high interest rates and low revenue levels led to a serious financial crisis in agriculture. The quantitative easing policies adopted by the Federal Reserve beginning in 2008 have lowered interest rates to historically low levels, which, in turn, have led to a substantial reduction in farm interest expenses relative to farm revenue. Another factor involved here is the weakening of the US dollar as interest rates decline, which has increased revenue from exports of agricultural production.

Another story line revealed in the sector income accounts is the declining role played by government payments to agriculture as farm incomes have achieved record levels. Figure 6 shows that government payments to producers principally in the form of deficiency payments when crop prices were low leading to the ethanol boom played a substantial role in bolstering net farm income. Beginning in the mid-2000s, however, this role has been substantially reduced to fixed direct payments, which are more likely to be eliminated in new farm legislation as a greater role is envisioned for crop insurance.

Sector balance sheet account

The US Department of Agriculture began to publish a balance sheet for agriculture in the 1940s. This account presents a

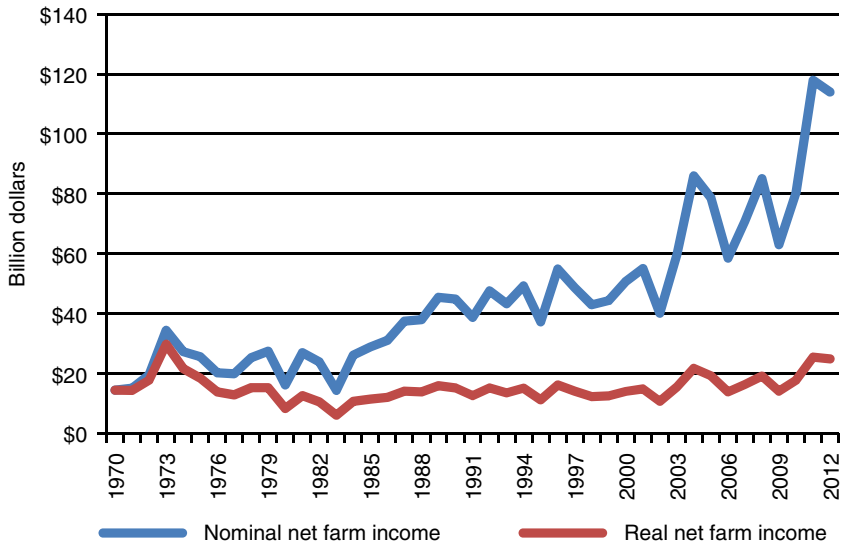

Figure 4 United States' net farm income.

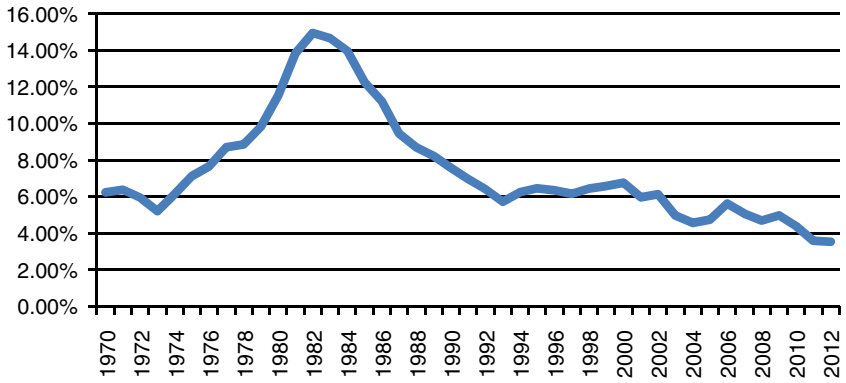

Figure 5 Interest expenses decline.

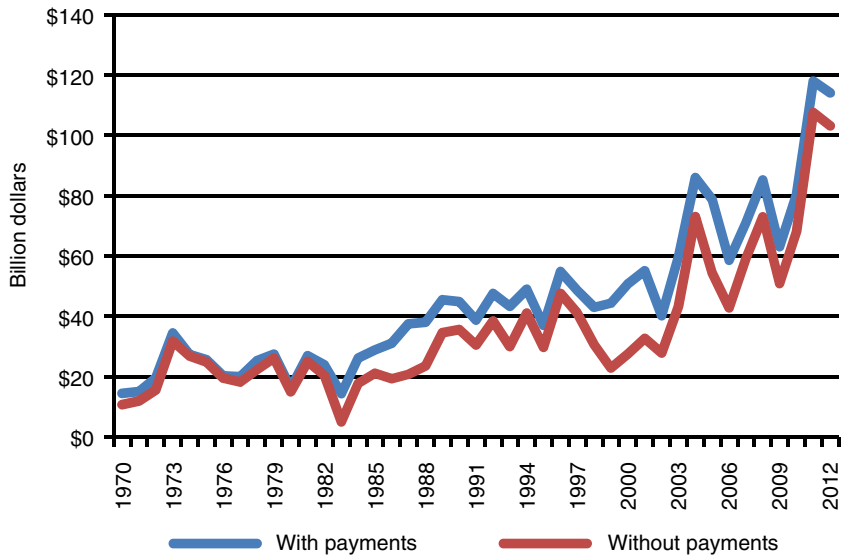

Figure 6 Importance of government payments.

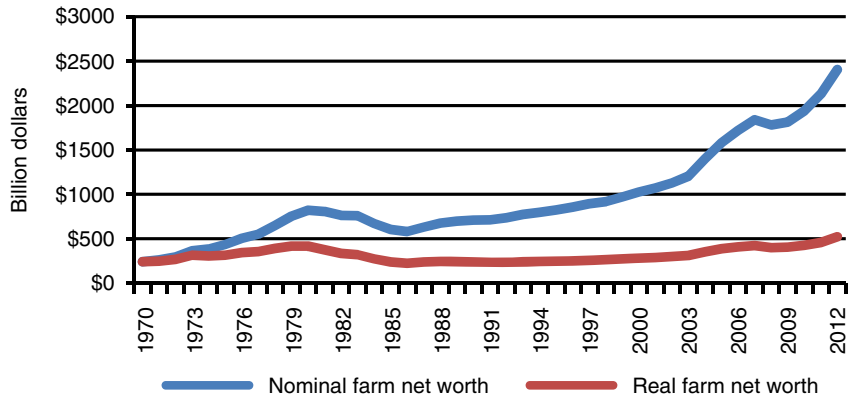

Figure 7 Nominal and real farm net worth.

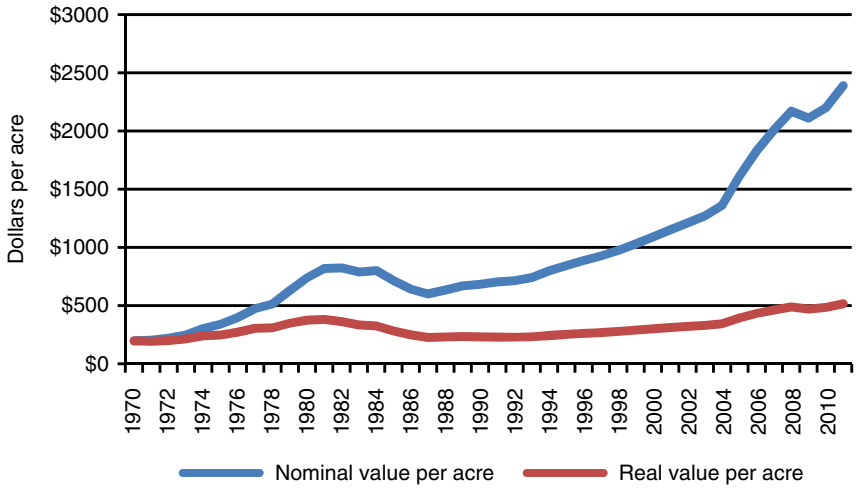

Figure 8 US value of farmland per acre.

measure of liquidity, solvency, and wealth of farm businesses as of 31st of December each year. The asset coverage in this account includes the current market value of farmland, farm buildings, livestock on farms, crop inventories, farm machinery, and other production inputs. This coverage also includes financial assets held for farm business purposes. The liability side of this balance sheet provides information on year-end farm real estate and nonreal estate debt outstanding. The debt ratio published with this account represented the major aggregative financial indicator used by analysts for many years. A maturing farm sector, where many family-owned farms have little or no farm debt outstanding, has reduced the interpretive value as a financial indicator at the sector level.

Figure 7 illustrates the growth trend in nominal and real farm net worth over the past five decades. This figure shows that although real net worth thus far in the 2010s is not appreciably different from what it was before the farm financial crisis in the early 1980s, the nominal value has increased substantially. This has further helped to reduce the debt ratio, particularly since the mid-2000s when the ethanol boom began in earnest. Thus, the real wealth position of farm asset owners at year-end in 2012 is slightly higher than what it was before the farm financial crisis in the early 1980s.

Much of the growth in farm net worth can be attributed to rising farmland values, particularly in feed grain-producing regions of the country. Figure 8 shows the trend in nominal and real farmland values per acre over the past five decades. Many mid-western states have realized double-digit increases in nominal farmland values since the mid-2000s; thanks to the growing demand for ethanol feed stock as well as a growing demand for agricultural products in emerging economies, like China.

In addition to these sector accounts published at the national level, the US Department of Agriculture periodically published the income and balance sheet accounts on a state basis for those desiring to conduct regional or state-level analyses. Other related data important to macroagricultural finance researchers contained in publications or websites maintained by the US Department of Agriculture include measures of productivity and efficiency, costs of production for crop and livestock operations, and trends in agricultural resource use.

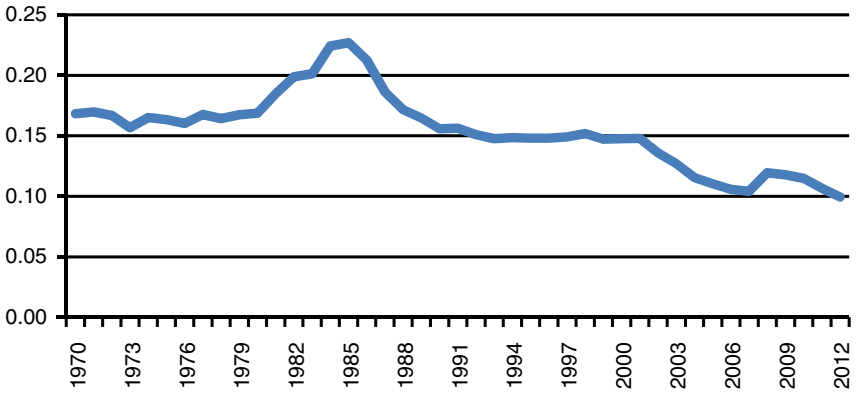

Figure 9 Sector debt-to-asset ratio.

Other sector financial information

The income statement and balance sheet accounts provide the basis for other assessments of macroagricultural finance. An example is the development of a sector-level annual sources and uses of funds statement. This would capture sources of funds from farm revenue and net borrowings as well as uses of funds attributable to cash farm operating expenses as well as capital expenditures for machinery and structures. The difference between these sources and uses of funds would explain the net increase in financial assets.

The income statement and balance sheet accounts, along with other available data, can also serve as the basis for calculating an aggregative set of financial indicators for the sector. This includes measures of liquidity, solvency, profitability, efficiency, and debt repayment capacity. Figure 9, for example, illustrates the trend in the farm debt ratio, which has declined sharply from the levels seen during the farm financial crisis in the mid-1980s. The US Department of Agriculture publishes a national-level time series indicating the used borrowing capacity at the sector level. One can construct similar series at the state or regional level using available state publications.

Other analyses possible using data from the US Department of Agriculture include a comparison of market value farmland values versus their capitalized values using published time series data on rents and the 10-year constant maturity government bond rate.

Research applications

The information contained in the US Department of Agriculture's sector economic accounts and related data sets is not only useful in current situation analysis but also represents a major source of data for research designed to project the effects that a broad range of macroeconomic, farm commodity, and international trade policies can have on the economic growth and financial performance of agriculture. Researchers dating back to the early 1950s have been developing statistical-based models of agricultural activity using, to varying degrees, information contained in these and related time series published by the US Department of Agriculture.

Although the sector provides a rich database to support positive and normative analysis of its structure and performances, the potential for aggregation bias is significant. Drawing implications from national data and models can lead to misleading conclusions regarding the financial health of the sector. Greater disaggregation of the accounts by major types of farming operations on a regional basis can help to avoid these issues. For example, assessments based solely on a national farm debt ratio, debt coverage ratio, or measures of unused borrowing capacity are examples of indicators that can contribute to misleading conditions facing farm financial institutions.

Modeling Aggregate Financial Performance

A second dimension to macroagricultural finance research has to do with understanding and projecting aggregate investment expenditures, farmland values, and the financial structure of the farm sector. Considerable resources have been committed to modeling these aggregate time series over the post-World War II period in both public and private sectors.

Modeling farm sector investments and asset values

Early studies of aggregate investment expenditures in agriculture focused principally on farm tractors. Many of these studies made overly simplifying assumptions with respect to the cost of capital and measurement of capital stocks and flows. These studies were followed by more rigorous efforts to expand the cost of capital to include monetary and fiscal policy-related variables as well as an accounting of the physical deterioration of an input's productive capacity, or capacity depreciation, across different vintages and types of machinery. This allows researchers to capture the direct and indirect effects of changes in macroeconomic policy on the investment expenditures that impact the productive capacity in agriculture. Modeling the demand for fixed assets should also reflect portfolio balance considerations with desired financial asset holdings.

There have been many studies focusing on explaining the determinants of farmland market values using a wide variety of quantitative approaches. Some researchers have focused on the capitalized value of farmland per acre as opposed to the market value, noting the disparity between these two time series in the early 1980s to mid-1980s when market values were slow to adjust to changing economic conditions affecting rents and interest rates. The ability to project the effects that

changing economic conditions brought about by policy and other factors enables lenders and others visualize how these events might alter the demand for debt capital in agriculture and the financial strength of crop and livestock producers.

Modeling farm sector financing

Attempts to model and project the annual borrowing and repayment of loans to agriculture have been largely unsuccessful due in part to a lack of data. For example, the annual flow of loan funds to financing farm operating expenses is unknown. The sector balance sheet account allows a measure of annual changes in real estate and nonreal estate debt outstanding from one year to the next. But this omits that portion of loan funds borrowed annually by producers that is used and repaid within the year. Data on interest expenses on real estate and nonreal estate loans potentially omit the interest expenses on short-term borrowing as well as the use of credit cards and lines of credit used and paid down during the year. The growing dichotomy between the size of farming operations and ownership structure makes it difficult to model aggregate farm financing behavior.

Key Linkages to Rest of the Economy

Previous mention was made of the effects that macroeconomic policies (domestic and global) have on the financial strength and performance of US agriculture. Researchers focusing on modeling the potential impact of these policies have to decide to what degree they want to endogenize the interface between agriculture and rest of the economy.

This issue can be viewed from several perspectives, including the interface between the domestic and global economy and whether to treat this interface as entirely exogenous, recursive, or simultaneous. The latter two choices require considerable time and resources. Input–output models and CGE models by definition endogenize the linkage between agriculture and the general economy. Econometric models, either structural or time series in design, also capture links to the domestic economy in various ways. Few, if any in recent years, capture these linkages in a fully simultaneous manner.

Domestic linkages

The interface between agriculture and the domestic economy occurs where producers acquire inputs (including loan funds) as well as in the markets where they sell their production. (The large integrated firms in the broiler, turkey, egg, and hog businesses frequently endogenize many of these relationships with the firm, thereby increasing the efficiency of their operations.) Furthermore, policy actions and other economic shocks occurring outside agriculture can be transmitted to crop and livestock producers in these markets. For example, research has shown that monetary policy directly affects the current operations and growth of agriculture through the cost and availability of loan funds. This represents a direct linkage between the policy action and the farm borrower. This same monetary policy, however, has an impact on other sectors of the economy as well and thus can alter the equilibrium levels of prices in all markets.

There are four major linkages between agriculture and the domestic economy. These variables are (Penson *et al.*, 2014):

- Interest rates – Producers generally borrow significant amounts of operating capital to finance current operations. Those modernizing their machinery or expanding the size of their operations also borrow a significant amount of debt capital to finance asset acquisitions. Thus, a one percentage point rise in interest rates will affect interest expenses and hence net farm income.
- Rate of inflation – Producers are generally price takers in the markets in which they buy variable and fixed production inputs. Sellers in these markets typically have the market power that enables them to pass along increases in their costs to producers.
- Unemployment rate – Many producers either work themselves or have a spouse and family members who work off the farm or ranch. Off-farm income represents a significant source of internal funds, particularly for small- or mid-sized farms that have a seasonal farming operation. An increase in the unemployment rate reflecting tighter employment opportunities and layoffs can affect this source of funds, and
- GDP growth rate – The economic growth of the economy can affect consumer disposable income and hence their demand for goods and services. Agriculture is less directly affected by economic growth in the domestic economy than the demand for durable goods and services. This is evidenced more by the low-income elasticity of demand for agricultural products (less than one) than by that for nonfood products.

The record levels of net farm income in the 2010s thus far have been helped by historically low interest rates and inflation rates. Studies focusing on demand systems for food products have provided estimates of elasticity for a wide range of commodities. Results suggest an inelastic demand and low-income elasticity for agricultural products. This has implications for price variability as supply shifts and muted effect of changes in disposable personal income as conditions change in the economy. Agriculture fared relatively well during the 2007–09 recession when most sectors exhibited weakened performance.

International linkages

Another factor contributing to record net farm income levels in the 2010s is the net export demand for agricultural products. This has been aided by a weak US dollar versus currencies of exporting nations. Considerable attention has been given in the literature to modeling international agricultural trade flows, including the effects that changes in foreign currency exchange rates can have on net exports for specific agricultural commodities like wheat and corn. The implication for finance is that low exchange rates can induce exports of agricultural products and vice versa. The record levels of net farm income in the 2010s thus far have also been helped by historically low value of the dollar.

The global financial crisis following the 2007–09 US recession has had an impact on all nations to varying degrees. The European Union and euro zone nations, for example, were

seriously affected by this crisis, with many nations continuing to deal with recessions long after the US economy began to expand. Although this has affected net exports to that market, many emerging nations, like China and India, with populations experiencing rising per capita income levels, continued to represent a strong export market for the US agricultural products.

Role of Policy

An important dimension to macroagricultural finance is the impact that macroeconomic, farm commodity, international trade, and other policies have on agriculture and the rest of the food and fiber industry. In discussing each of these areas, it is important to distinguish between the general impacts of these policies, in addition to their financial implications.

Macroeconomic policy impacts

Macroeconomic policy makers want to know the likely effects of their actions not only in the general economy but also specific sectors in the economy like agriculture. Not all sectors are affected the same when a policy change or economic shock occurs in the economy. Perhaps no other sector exhibits the unique direct and indirect effects from a macroeconomic shock like agriculture. Of interest here is the fact that a large share of the 'cause and effect' is financial in nature. Table 1 summarizes the likely short run effects specific combinations of monetary and fiscal policy have on agriculture.

The 2007–09 recession in the US economy, referred to by some as the Great recession because of its duration, occurred at a time when interest rates were already low. Hence, the traditional tools employed by the Federal Reserve to stimulate the economy were off the table. With an effective federal funds rate near zero, the Federal Reserve turned to extraordinary tools to provide liquidity to the economy and keep long-term interest rates low. A series of three quantitative easing (QE) initiatives began in 2008 involving purchasing agency securities and mortgage-backed securities. These purchases reached US$85 billion a month in 2013. The levels of these purchases were tied to targets for the civilian unemployment rate and PCE-based inflation rate. This approach was augmented by 'operation twist' beginning in late 2011 that involved the Federal Reserve buying long-term securities while selling short-term securities in an effort to keep long-term interest rates low.

Agriculture is typically a beneficiary of expansionary macroeconomic policies. Although the unemployment rate has remained sticky above the Federal Reserve's target, interest rates, inflation, and the foreign exchange rate – three important macrovariables for agriculture – fell to historic lows. This helped to lower interest expenses (Figure 5), to avoid inflationary pressures pushing up input costs, and helped to make US agricultural products more affordable to emerging economy nations, like China.

Several fiscal policy actions during the 2007–09 recession, including stimulus checks and bailouts of General Motors, Chrysler, and AIG, helped the economy by minimizing the depth of the 2007–09 recession. However, fiscal policy makers did little to alleviate the uncertainty about future taxation and spending programs following the recession. This uncertainty created an environment where businesses in general and financial markets remain conservative regarding future expansion. This environment has had a much greater impact on other sectors of the economy like housing than it had on agriculture.

Farm commodity policy impacts

The federal government has a long history of supporting prices and incomes in agriculture when the need arose. Low commodity prices for major crops, like corn and wheat, have traditionally meant higher deficiency payments paid to producers participating in these farm programs (Figure 6). These policies affect the level of sales activity in backwardly linked farm input sectors as well as forwardly linked food processing sectors. These payments have also helped to stabilize farm financial markets by aiding producers' debt repayment capacity. Such support programs, to the extent they are expected to continue, are capitalized into the valuation of long-term assets, like farmland.

With the farm program legislation up for renewal, the Senate and House appear to support a greater role for federally subsidized crop insurance programs designed to offer varying degrees of yield and revenue support tied to premium rates paid by participating producers. Limited revenue insurance programs to date have been available to livestock producers. Agricultural lenders typically require borrowers to verify that

Table 1 Impacts of macroeconomic policy on agriculture

Policy effects on	*Expansionary monetary policy*	*Expansionary fiscal policy*	*Contractionary monetary policy*	*Contractionary fiscal policy*
Crop price				
Domestic demand	Raise	Raise	Lower	Lower
Export demand	Raise	Lower	Lower	Raise
Net impact	Raise	Lower	Lower	Raise
Livestock prices	Lower	Raise	Raise	Lower
Farm input prices	Raise	Raise	Lower	Lower
Farm interest rates	Lower	Raise	Raise	Lower
Net farm income	Raise	Lower	Lower	Raise
Farmland prices	Raise	Lower	Lower	Raise

Note: Direction of change is not unambiguous, but rather conditional on the relative market share for export demand and relative price elasticity of export demand. A relatively high market share or relatively high price elasticity of export demand is assumed in this table. It is assumed the impact on crop prices and interest payments offsets the impacts on livestock prices when calculating net farm income and farmland prices for both crop and livestock producers.

they are a participant in federal support programs, like crop insurance.

Resource policy impacts

Agriculture is a dominant user of the United States' natural resources, such as water, timber, and land. Numerous government agencies, such as the Environmental Protection Agency, the US Department of Agriculture, and the US Department of the Interior, have supervisory jurisdiction over the use of these resources and associated use of manufactured resources like agricultural chemicals. In recent years, many have become concerned with pollutants in water supplies and carcinogens in food supply caused by agricultural production practices.

Resource policy concerns have led to bans on the use of specific agricultural chemicals in the production of food grains and other crops. Reductions in yields and hence net farm incomes could vary regionally depending on the level of input use required to achieve a desired yield. The economic performance and financial position of farm borrowers would vary accordingly, with crop producers in northern regions faring better than crop producers in the more temperate southern regions, and with crop producers in general being less affected financially than livestock producers.

Trade policy impacts

Crop agriculture has become export dependent. Typically, more than one-fourth of all agricultural production is exported, accounting for roughly one-third of farm income. Wheat, cotton, and rice are major crops depending on export markets as a major source of demand. Horticultural products and meats are less export dependent than row crops, although their market shares are increasing. A strong export demand has indirect ramifications in backwardly linked input supply sectors and forwardly linked processing and trade sectors in the US food and fiber industry.

Distortions to agricultural trade in the form of tariffs and quotas have prompted major trading nations to participate in the General Agreement on Tariffs and Trade. These negations typically liberalize trade in agricultural products. Exchange rates, influenced by monetary policies of trading nations, have become one of the most important economic variables affecting US agricultural trade in cases where exports account for a large share of production. For the most part, preferential trade agreements entered into by the United States have taken the form of free trade areas. The North American Free Trade Agreement is an example. Other forms of free trade zones include economic unions like the European Union.

Agricultural Labor: Demand for Labor

WE Huffman, Iowa State University, Ames, IA, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

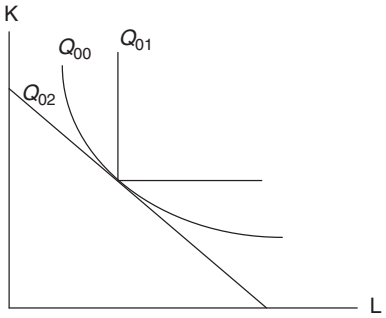
Capital Services of a machine, equipment, or building.
Isoquant A graph showing all combinations of inputs (labor, capital, and materials) needed to produce a particular amount of output with given technology.
Labor Services of a worker or laborer.
Labor demand Derived from the demand for the output, given the prices of output and inputs and technology.
Materials Intermediate inputs, for example, fertilizer, pesticides, seeds, fuel, and electricity.
Production function The relationship of output (volume of produce, goods, or services) to inputs (labor, capital, and materials) and technology.
Technology The result of specific application of information or knowledge which results in a particular algebraic relationship among output and inputs, or technical efficiency of production.

Introduction

Agriculture has historically been a sector characterized by much hard physical labor performed sometimes under adverse weather and environmental conditions. However, farming in the US has advanced through oxen, horses and mules, steam tractors, and then tractors with internal combustion engines to provide power on farms. Tractors started to be a competitive source of power in the early twentieth century, as progress moved from steam to internal combustion engines and steel to air-inflated rubber tires. Early reapers and binders were forerunners of stationary threshing machines, and mobile combines or mechanical harvesters for grain, beans, and cotton became available over 1930–1960s. However, hand harvesting of fruits and vegetables continued into the late 1960s. The invention and later adoption of the self-propelled mechanical processed tomato harvester in the mid-1960s was a major labor-saving factor in fruit and vegetable harvesting. However, with later related inventions, further saving in labor and improvement in product quality were the result. Mechanical harvesters were developed for some other processing fruits. Although fresh fruit and vegetable harvesting continues largely by hand, mechanical aids have made harvesting faster and with less stress on workers' backs.

US agriculture competes with other sectors of the economy for inputs of labor, chemicals, building materials, and land. Since 1980s, an increase in international competition in grains, oilseeds, fruits and vegetables, and livestock and livestock products has occurred with, for example, Mexico and Chile, as low cost suppliers of fresh fruits and vegetables (Calvin and Martin, 2010). However, for an extended period, US growers have drawn on illegal and legal workers from Mexico as sources of planting and harvesting labor in these crops. In particular, mechanization and modification of production practices and improved management practices have been central to reducing labor requirements for the growing and harvesting of all kinds of crops. Calvin and Martin (2010) report that mechanical harvesting is most prevalent in horticultural crop harvesting, being 75% of vegetables and melons and 55% of fruits. In 2009, the largest (harvested) volume of US fruit and vegetable crops (in millions of tons) are: tomatoes (15.6), oranges (9.2), grapes (7.3), apples (5.0), potatoes (4.1), melons and cantaloupes (3.2), head lettuce (2.5), sweet corn (1.5), strawberries (1.4), and carrots (1.1) (USDA, NASS, 2011a,b,c).

This article provides a long-term perspective on the demand for farm labor in the US. It does this by taking up the following topics: (1) the economics of labor demand (the conceptual economic model of production and supply of output and demand for inputs); (2) mechanization of agriculture in the nineteenth and twentieth centuries (also see Huffman, 2012); (3) substitution of biological advances and chemicals for farm labor and other agricultural materials; (4) more on mechanization of fruit and vegetable harvesting; (5) structure of farms; (6) estimates of the wage elasticity of demand for farm labor (from aggregate data); and (7) conclusions.



In the long history of agriculture, mechanization has generally required a transformation of a farming system, for example, new machinery, larger field sizes, new crop varieties, new field configurations, and new harvesting and storage/packing equipment, storage facilities and processes. In addition, a significant capital outlay is frequently required. A better picture of all of this unfolds in the following pages.

The Economics of Labor Demand

To set the stage for a deeper understanding of the economics of labor demand, the author develops some terminology associated with a farm output production function, farm profit maximization and input demand. Consider a production function for a single output (Q) that uses inputs of labor services (L), capital services (K), and materials (X):

$$Q = F(L, K, X, \tau) \quad [1]$$

In agriculture, farm labor includes the farm operator, unpaid family labor and other labor hired by the farm operator or manager, but contract farm labor, fertilizer, and pesticide application and custom harvesting are part of the materials.

Note:

$Q = F(L, K; \tau)$

$\Delta Q = MP_L \Delta L + MP_K \Delta K = 0$

$MP_K \Delta K = -MP_L \Delta L$

$\therefore MRS_{KL} = \dfrac{\Delta K}{\Delta L} = -\dfrac{MP_L}{MP_K}$

Q_{00}: *K* and *L* with generally variable input ratios or combinations (curved isoquant)

Q_{01}: *K* and *L* used in fixed proportions (right angle isoquant)

Q_{02}: *K* and *L* are perfect substitute 1-to-1 (straight line isoquant)

Figure 1 Isoquant showing combinations of capital (*K*) and labor (*L*) to product Q: variable input proportions, fixed proportions and perfect substitutes.

Generally, materials include farm feed, pharmaceuticals, fuel, seeds, farm purchased fertilizers and pesticides, and utilities.

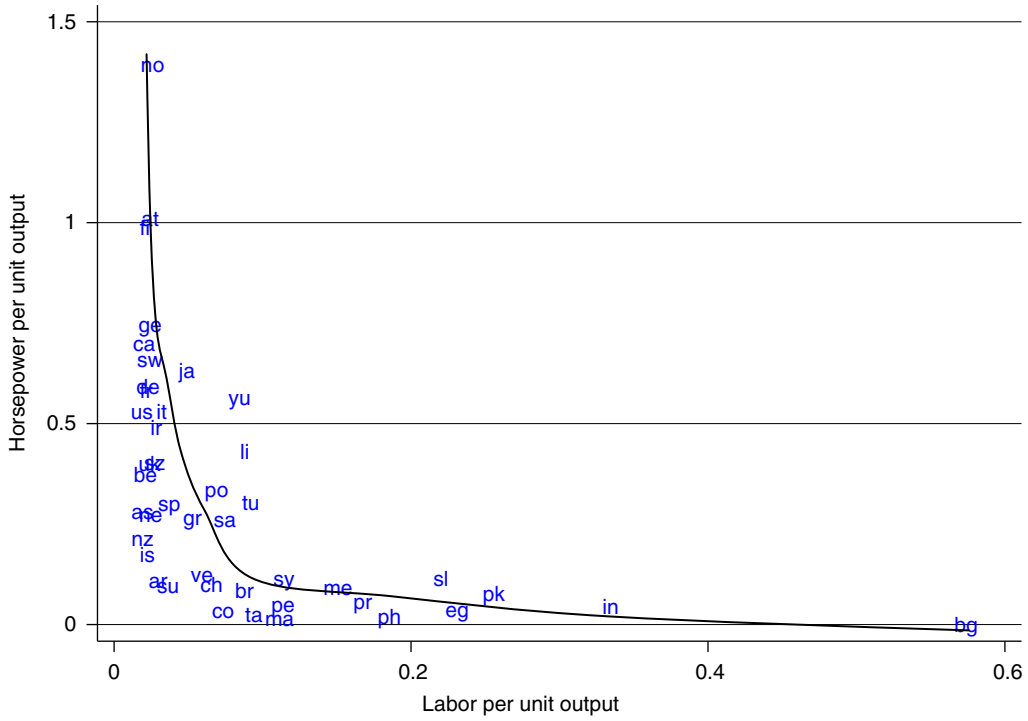
In eqn [1], τ is an efficiency parameter that summarizes how effectively labor, capital, and materials are converted into output Q, either neutrally or in a biased way. We will proceed for now assuming that it is fixed. For eqn [1], the marginal product (MP) of labor (marginal change in Q because of a marginal increase of L) is denoted as $\partial Q/\partial L = MP_L(L, K, X, \tau)$. Likewise the MP of capital (K) and materials (X) are $\partial Q/\partial K = MP_K(L, K, X, \tau)$ and $\partial Q/\partial X = MP_X(X; L, K, \tau)$, respectively.

An isoquant is the graph used by economists to display the combinations of L, K, and X required to produce a given amount of output, Q_0. Mathematically, they are simply level curves of a multivariable function, which in this case is a production function. Figure 1 shows three different types of technical relationships between inputs of labor and capital for producing a given quantity, Q_0 With the isoquant labeled Q_{00}, there are general-variable factor proportions or a wide range of ratios of K to L that will produce the given quantity of output. With Q_{01}, the inputs must be used in fixed proportions, say one unit of capital and one unit of labor to produce one unit of output. Additional labor (capital) without additional capital (labor) does not produce any additional output. For example, roughly fixed proportions exist between tractor drivers and tractors, but of course the size of tractor and skill of the operator can differ and in this way effectively change the proportions. Also, by having multiple drivers, the tractor can be operated nearly 24 h per day. With Q_{02} the inputs are perfect substitutes, for example, one unit of capital and one unit of labor are interchangeable in the way that they impact Q_0. In the case of perfect substitutes, a better example is using male labor with blue and brown eyes. They are interchangeable with no impact on production.

Hayami and Ruttan (1985) have assembled some data on labor (workers) and capital (measured in horsepower) to produce wheat in 44 countries. Orazem (1998) has converted this information into a unit isoquant, which graphs combinations of capital and labor required to produce a single bushel of wheat. See Figure 2, which has the usual 'convex to the origin' shape revealing general substitution possibilities between capital and labor for wheat across countries that have very different wage to capital rental rates.

The most notable production function is the (general) Cobb–Douglas (C–D), which relates output Q to a special power function in input quantities (Douglas, 1976).

$$Q = AL^{\alpha}K^{\beta}X^{\gamma}, A = A(\tau), \quad 0 < \alpha, \beta, \gamma < 1 \qquad [2]$$



Its MPs are proportional to the average products (APs) in a special form; for labor, $MP_L(L, K, X, \tau) = \alpha AL^{\alpha-1}K^{\beta}X^{\gamma} = \alpha Q/L = \alpha AP_L(L, K, X, \tau)$. Likewise, for capital, $MP_K(L, K, X, \tau) = \beta AL^{\alpha}K^{\beta-1}X^{\gamma} = \beta Q/K = \beta AP_K(L, K, X, \tau)$, and for materials, $MP_X(L, K, X, \tau) = \gamma AL^{\alpha}K^{\beta}X^{\gamma-1} = \beta Q/X = \gamma AP_X(L, K, X, \tau)$. Under an assumption of the C–D production function, Figure 3 displays the marginal product of labor against the labor per unit of output (bushel of wheat) for 44 wheat-producing countries (Orazem, 1998). For small amounts of labor it shows rapidly diminishing marginal product of labor, and then the rate of decline slows and the marginal product remains relatively unchanged for large amounts of labor per unit of wheat.

Returning to eqn [2], if there is constant returns to scale in using L, K, and X to produce Q, then a doubling in each of these inputs results in a doubling of the output (Q), or $\phi = \alpha + \beta + \gamma = 1$, but, generally, one expects there to be decreasing returns to scale – a doubling of inputs results in less than a doubling of output.

For farms or the farm sector, a standard assumption made by economists is that farmers accept the price asked for by suppliers of inputs and take the price offered to them by buyers of their output – roughly competitive markets for output and inputs reign. In the short run, it may be plausible to assume that capital (K) and material (X) are fixed, and labor (L) is variable. Under these conditions, what is the optimal amount of labor to use? Note that short-run profit is defined as

$$\pi_S(P_Q, W_L, \bar{K}, \bar{X}, C_0, \tau) = P_Q F(L, \bar{K}, \bar{X}, \tau) - W_L L - C_0 \qquad [3]$$

where W_L is the wage rate or opportunity cost of one unit of labor and C_0 are fixed costs, possibly associated with fixed

$$Elasticitiy - of - substitution = \sigma_{KL} = \%\Delta\left(\frac{K}{L}\right) / \%\Delta\ \left(\frac{W_L}{W_K}\right) \geq 0$$

Figure 2 Labor and capital (as horsepower) use per unit of agricultural (wheat) output. Data across 44 countries. Figure was constructed from data reported in Hayami, Y., Ruttan, V.W., 1985. Agricultural Development: An International Perspective. Baltimore, MD: Johns Hopkins University Press.

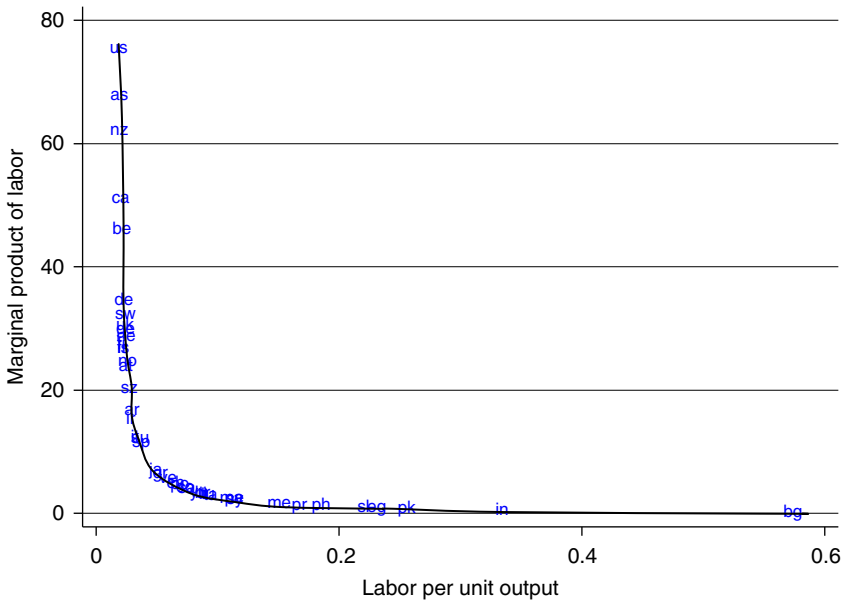


Figure 3 Marginal product of labor as a function of the quantity of labor. Data on wheat equivalent production across 44 countries. Figure was constructed from data reported in Hayami, Y., Ruttan, V.W., 1985. Agricultural Development: An International Perspective. Baltimore, MD: Johns Hopkins University Press.

K and X. The optimal usage of labor occurs when $\partial\pi/\partial L = P_Q \partial Q/\partial L - W_L = P_Q MP_L(L,\bar{K},\bar{X},\tau) - W_L = 0$, provided profit at an optimum is positive, or the value of the marginal production of labor is equal to the wage rate. In the C–D case, this condition reduces to $P_Q \alpha Q/L = W_L$, or the optimal short-run amount of labor demanded is

$$L_S^* = d_S(P_Q, W_L, \bar{K}, \bar{X}, C_0, \tau) \quad [4]$$

Figure 4 displays the short-run demand curve for labor with its characteristic negative slope – as the wage rate increases, the quantity demanded of labor declines, other things equal. For example, continuing with the example of wheat production, Figure 5 plots an approximation to the empirical demand for labor in wheat production across 44 countries, and also includes a graph fitted roughly through the frontier associated with these points. Under the assumption that farmers are using roughly the optimal short-run amount of labor, it shows that the value of the marginal product of labor is decreasing as more labor is used in wheat production. Moreover, Figure 6 plots the optimal capital-labor ratio as the real wage rate rises in wheat production across 44 countries.

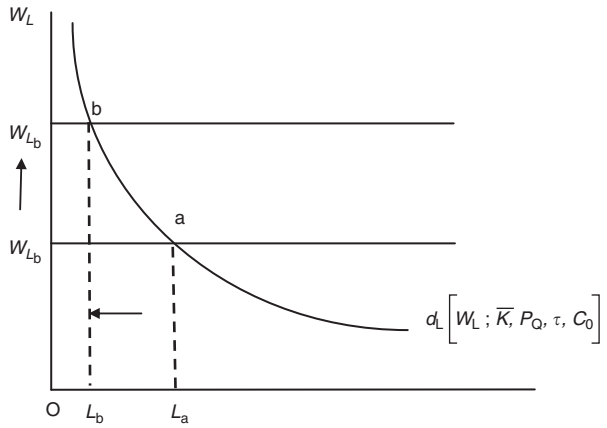

Figure 4 The short-run labor demand curve. W, wage.

Moreover, if eqn [4] is substituted into $Q = F(L,\bar{K},\bar{X},\tau)$, one obtains the short-run supply function for Q or

$$Q_S^* = S_L(P_Q, W_L, \bar{K}, \bar{X}, C_0, \tau) \quad [5]$$

Hence, the quantity supplied of Q varies with the output price, P_Q, which represents a movement along the short-run output supply curve; and with the wage rate, W_L. Moreover, when the wage rate increases, this increases the cost of production, other things equal, and the quantity supplied of output will be reduced or the supply curve for output will shift to the left (provided the firm does not shut down because profits are negative). The short-run supply curve has a positive slope – quantity supplied is positively related to the price as shown in Figure 7. At output price P_Q^0 the optimal output is Q_1 When the wage rate increases to W_{L_2}, the supply curve for Q shifts left and the new optimal output is Q_2.

In the long-run, labor (L), capital (K), and materials (X) are all variable, and all three of these inputs must be used optimally at the same time to maximize the long-run profit function:

$$\pi(P_Q, W_L, W_K, W_X, C_0, \tau) = P_Q F(L,K,X,\tau) - W_L L - W_K K - W_X X - C_0 \quad [6]$$

which, assuming positive labor, capital, and materials inputs, requires that the following conditions simultaneously hold

$$\partial\pi/\partial L = P_Q MP_L(L,K,X,\tau) - W_L = 0 \quad [7]$$

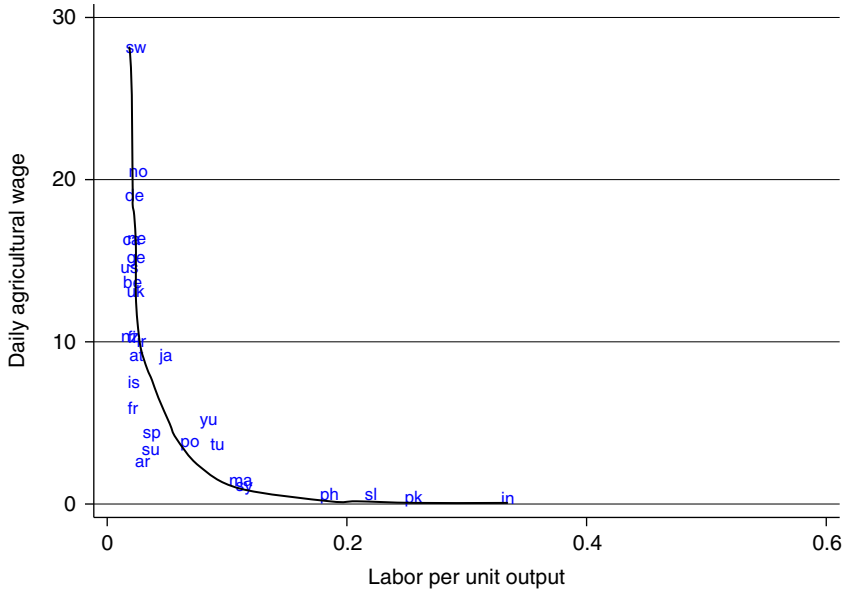

Figure 5 Short-run labor demand: labor use in wheat production across 44 countries. Figure was constructed from data reported in Hayami, Y., Ruttan, V.W., 1985. Agricultural Development: An International Perspective. Baltimore, MD: Johns Hopkins University Press.

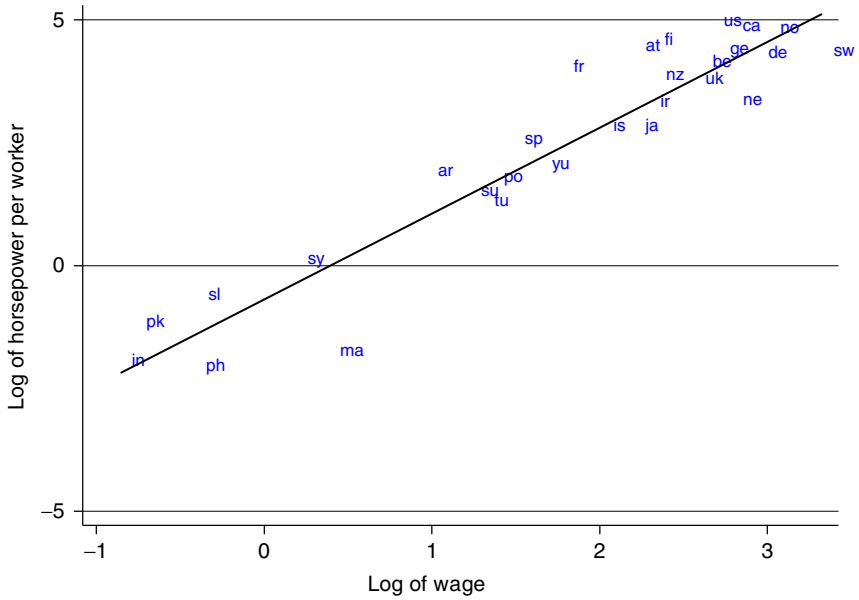

Figure 6 Capital per unit of labor as wage to labor rises: labor use in wheat production across 44 countries. Figure was constructed from data reported in Hayami, Y., Ruttan, V.W., 1985. Agricultural Development: An International Perspective. Baltimore, MD: Johns Hopkins University Press.

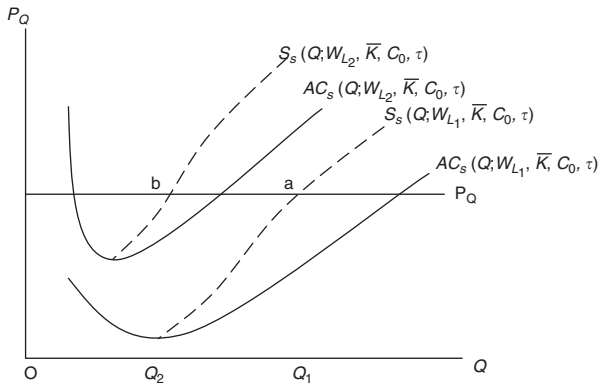

Figure 7 The short-run supply curve for output (Q). *P*, price.

$$\partial\pi/\partial K = P_{\mathrm{Q}} MP_{\mathrm{K}}(L,K,X,\tau) - W_K = 0 \qquad [8]$$

$$\partial\pi/\partial X = P_{\mathrm{Q}} MP_{\mathrm{X}}(L,K,X,\tau) - W_X = 0 \qquad [9]$$

$$\pi^*(P_{\mathrm{Q}}, W_{\mathrm{L}}, W_{\mathrm{K}}, W_{\mathrm{X}}, C_0, \tau) \geq 0 \qquad [10]$$

Equation [10] is the condition for the firm to operate at positive output, long-run profit at optimal input use must be positive, or zero. Moreover, when eqns [7]–[10] hold and the production function is strictly concave, one can solve these equations for the profit maximizing or long-run input demand functions.

$$L^* = d_{\mathrm{L}}(P_{\mathrm{Q}}, W_{\mathrm{L}}, W_{\mathrm{K}}, W_{\mathrm{X}}, C_0, \tau) \qquad [11]$$

$$K^* = d_{\mathrm{K}}(P_{\mathrm{Q}}, W_{\mathrm{L}}, W_{\mathrm{K}}, W_{\mathrm{X}}, C_0, \tau) \qquad [12]$$

$$X^* = d_{\mathrm{X}}(P_{\mathrm{Q}}, W_{\mathrm{L}}, W_{\mathrm{K}}, W_{\mathrm{X}}, C_0, \tau) \qquad [13]$$

What eqn [11] indicates is that in the long-run profit maximizing situation, the optimal amount of labor is determined by the price of labor, price of capital, price of materials, and by the fixed cost C_0, which will generally be different than in the short-run situation and might be smaller, as well as the technology parameter τ. Moreover as the wage rate for labor increases, the quantity demanded of labor decreases. The impact of an increase in the rental on capital W_{K} (price of materials W_{X}) could be to increase, reduce, or leave unchanged the demand for labor.

Maintaining the assumption of C–D production, one finds that the long-run demand for labor function is

$$\begin{aligned} L^* &= [\alpha^{(\beta+\alpha-1)}\beta^{-\beta}\gamma^{-\gamma}A^{-1}\cdot P_{\mathrm{Q}}^{-1} W_{\mathrm{L}}^{(1-\beta-\gamma)} W_{\mathrm{K}}^{\beta} W_{\mathrm{X}}^{\gamma}]^{1/(\alpha+\beta+\gamma-1)} \\ &= [A^* P_{\mathrm{Q}}^{-1} W_{\mathrm{L}}^{(1-\beta-\gamma)} W_{\mathrm{K}}^{\beta} W_{\mathrm{X}}^{\gamma}]^{1/(\alpha+\beta+\gamma-1)} \end{aligned} \qquad [14]$$

This has the unique attribute of being a power function in the output and input prices because of a duality (similarity) in the functional form of the production function and profit function (Beattie and Taylor, 1993). The long-run demand equations for capital and materials have a similar symmetric expression. From eqn [14], the wage (capital rental, materials price, output price) elasticities of labor demand, respectively, are

$$\eta_{L^* W_{\mathrm{L}}} = (1-\beta-\gamma)/(\alpha+\beta+\gamma-1) < 0 \qquad [15]$$

$$\begin{aligned} \eta_{L^* W_{\mathrm{K}}} &= \beta/(\alpha+\beta+\gamma-1) < 0, \\ \eta_{L^* W_{\mathrm{X}}} &= \gamma/(\alpha+\beta+\gamma-1) < 0 \end{aligned} \qquad [16]$$

$$\eta_{L^* P_{\mathrm{Q}}} = 1/(\alpha+\beta+\gamma-1) > 0 \qquad [17]$$

Note that increasing the size of α (which is proportional to labor's cost share) and holding $\alpha+\beta+\gamma$ constant increases the own-price elasticity of demand for labor. Also, as the size of $\alpha+\beta+\gamma$ (<1) increases, the positive output price elasticity of demand for labor increases.

On substituting the profit maximizing long-run input demand functions for L, K, and X from eqns [11]–[13] and rearranging, we obtain the long-run supply function for Q

$$Q^* = S(P_Q, W_L, W_K, W_X, C_0, \tau) \qquad [18]$$

which relates the quantity of Q supplied on to the output price, the three input prices, the technology parameter, and C_0. When the production function is C–D, as in eqn [2], and the input demand functions are of the form of eqn [14], and $\pi_L^* > 0$, the C–D supply function is

$$Q^* = P_Q^{(\alpha+\beta+\gamma)/(1-\alpha-\beta-\gamma)}[A(\alpha/W_L)^{\alpha}(\beta/W_K)^{\beta}(\gamma/W_X)^{\gamma}]^{1/(1-\alpha-\beta-\gamma)} \qquad [19]$$

From eqn [19], the elasticity of supply of Q with respect to the wage rate is

$$\eta_{Q^* W_L} = -1/(1-\alpha-\beta-\gamma) < 0 \qquad [20]$$

and the elasticity of supply of Q with respect to its own price is

$$\eta_{Q^* P_Q} = (\alpha+\beta+\gamma)/(1-\alpha-\beta-\gamma) > 0 \qquad [21]$$

It is important to note that the own-price elasticity of supply of Q changes at each point along the supply curve, holding the prices of the inputs, the technology parameter, and C_0 constant. However, an increase in the wage rate (rental on capital, or price of materials) causes the supply curve for Q to shift to the left, or reduces the optimal amount of output to supply.

In eqn [1], there is a technology parameter τ. We have proceeded under the assumption that whatever this technology is, it is fixed or unchanging. We now want to release this assumption because this permits a generalization of the production framework that we have developed above. It can also be interpreted as changing the effective number of units that we bring to the production process, or increasing the amount of available labor, capital, and materials. We focus on two general types of technical change: truly neutral and biased. To be truly neutral, when τ increases, it increases the marginal products of all three inputs by the same proportion or percentage (%). For example, for a given quantity of labor, capital, and materials, a 10% increase in the marginal products of all inputs will result in the possibility of producing 10% additional output at the same total cost, and the marginal cost of producing Q will decline by 10% and profit will rise by 10%. This seems highly beneficial for firm owners and input suppliers, but it would be misleading to believe that technical change is 'free:' to be sure, there are associated costs, privately or collectively (Huffman and Evenson, 2006).

To consider biased technical change, we shall limit our inputs to labor and capital, and then there are two types of bias: (1) labor saving (or capital using) and (2) capital saving (or labor using) at a given set of relative input prices producing an unchanged amount of output Q. Because much of the technical change in US agriculture can be viewed as labor saving (or capital using), we will consider this type further. Holding expenditures and input prices constant, we start at point a on iso-cost line C_0C_0', where the isoquant Q_{01} is tangent to it in Figure 8. After labor-saving technical change, we produce the same amount of output, but now the isoquant has rotated counterclockwise and becomes tangent to C_0C_0' at b, which is to the left of a. Hence, to produce the same amount of output and at the same resource costs in both situations, the optimal amount of capital to use increases from K_a to K_b, but the optimal amount of labor declines from L_a to L_b. This can only occur if, at the intersection of the two isoquants, the marginal product of labor has risen relative to the marginal product of capital. One might ask how this could occur. The new technology must increase the marginal product of labor relative to the marginal product of capital for all input combinations, that is, make labor more productive. Regarding input demand at given input and output prices, this labor-saving technical change will increase the demand for capital and reduce the demand for labor. Moreover, this type of change is necessary for economic growth, which simultaneously requires food production to increase so as to release labor so that it can migrate out of agriculture and obtain nonfarm employment. Although some of these adjustments will be taken up in the next section, Huffman and Orazem (2007) have a more extensive discussion of the structural adjustments that must accompany modern economic growth and development.

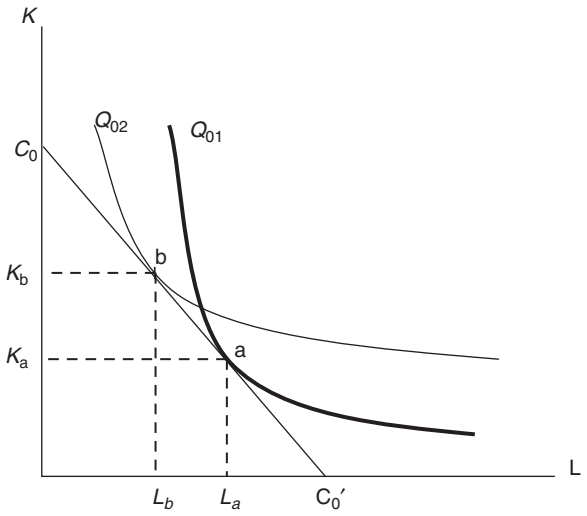

Figure 8 Labor saving (or capital using technical change). *C*, cost.

This section provides the theoretical and empirical foundations of labor demand. It shows that the demand for labor depends on input prices, technology, and the price of the output produced. A change in any one of these factors will change the quantity of labor demanded. When the price of durable goods declines, as when new equipment becomes available to farmers, this may cause labor-saving technical change as well as a substitution away from labor toward machine services. Cheap immigrant farm labor has kept wage rates low for fresh fruit and vegetable harvesting, and this has caused the quantity of labor demanded to be larger than it might otherwise have been. However, progress has been made

in developing mechanical harvesters for agricultural products that undergo further and generally off-farm processing. The invention of pesticides has also been labor saving and materials input using. Farm size has been somewhat conditioned by the amount of work that 1.5 full-time equivalent person years can undertake, but with a long sequence of labor-saving technical changes, farm size has increased dramatically in terms of the volume of output(s) that can be produced, whereas keeping the amount of farm labor used relatively unchanged. Finally, the theoretical framework provides a basis for econometric models that can be used to estimate coefficients needed to derive own-price and cross-price elasticity of demand for labor in agriculture. These topics are taken up in the following sections.

Mechanization of US Agriculture in the Nineteenth and Twentieth Centuries

The abundance of free land ended in the US at about 1890, at which time the application of science to the development of new agricultural technologies started (Huffman and Evenson, 1993). In particular, the Hatch Act of 1887 was passed to endow each state with support for establishing and maintaining state agricultural experiments at land grant universities. Rapid growth in the US population ended in 1920 with the imposition of a new immigration policy that imposed strict quotas by national origin.

Farm mechanization in the US took the form of substituting tractors for human and animal power. Olmstead and Rhode (2008) call the period 1840–1910 the 'great period' of US farm mechanization; certainly, this is the first great mechanization period. The adoption of new farm technologies was closely tied to the adoption of horses and mules, as opposed to oxen or human labor for power on US farms. They suggest that a common definition of farm mechanization is the adoption of a machine that allows farmers to substitute animal (horse)power for human labor, thereby enabling a farm worker to cultivate more area (or harvest more grain, cotton, or hay) per day or week. They report that in a sample of 628 Illinois farmers in 1860, mechanical reaper owners possessed 5.9 horses and mules and 0.43 working oxen – twice the ratio of equine to bovines found in the sample area of Illinois in the general population of farmers. The new reapers were associated with the use of a faster draft mode and complementary biological advances (improved crop varieties). They also document that from 1850–1910, farm acres per worker increased as horsepower per worker increased.

The invention and improvement of gasoline farm tractors was central to long-term mechanization. The early farm tractors were behemoths, patterned after the giant steam tractors that proceeded them – some weighing 10 ton but yielding relatively little drawbar or towing horsepower (10–30). They were, however, somewhat more efficient in developing belt-power or stationary power. These tractors were used for plowing, harrowing, and belt work but not for cultivating fields of row crops or for powering farm equipment in tow. Innovative advances between 1910 and 1940 dramatically reduced the size and weight of these tractors and increased their versatility, so that they were now useful for a much wider range of farm tasks. Importantly, these new tractors weighed less than 1 ton.

Olmstead and Rhode (2008) report that The Bull (first available in 1913) was the first small and agile tractor, Henry Ford's popular Fordson (first available in 1917) was the first mass-produced entry, and the McCormick-Deering Farmall (first available in 1924) was the first general-purpose tractor capable of cultivating row crops, such as corn and cotton. The Farmall was the first gasoline-powered tractor to incorporate a power takeoff, which enabled it to transfer power directly to implements under tow. Allied innovations such as improved air and oil filters, stronger implements, pneumonic rubber tires rather than steel wheels, and the Ferguson hydraulic three-point hitch system greatly increased the tractors' lifespan and reduced the work of farmers and animal power. The reduction in weight and increase in versatility of tractors was primarily a consequence of the change from steel wheels to rubber tires, and this also extended machine life because of reduced vibrations, increased the usefulness of tractors for hauling wagon loads of materials on roads and increased drawbar pulling efficiency by a large magnitude. Farmers could also move much faster and more easily travel to widely dispersed fields for field work.

In 1910 there were negligible number of tractors on US farms and approximately 23 million draft animals. Because tractors were making slow progress to the late 1910s and the number of draft animals on farms was somewhat increasing, draft animals were growing in number relative to tractors until about 1917. After that, the number of farm tractors on farms steadily and measurably increased, and as this occurred, the number of draft animals declined. By c. 1943 there were equal numbers of draft animals and tractors on US farms, approximately 13 million, but the trends accelerated after the end of World War II, when new farm machinery became readily available again. By 1960, the source of power on US farms had totally reversed – largely tractors and only a few draft animals (Olmstead and Rhode, 2008, p. 374).

With the advance of tractors came inventions and innovation in mechanical combines and corn and cotton pickers. These were immensely labor-saving technologies. When harvesting of corn was by hand, as it was in the US Midwest to the late 1940s, a good husker could pick only approximately 100 bushels per day. Horse-drawn corn huskers and pickers first became available in the 1920s, but they were not very effective, especially in wet field conditions. Power driven mechanical corn pickers (of the corn ear) were not possible until tractors were developed with live power takeoffs (Bogue, 1983). Moreover, low pressure pneumatic rubber tires on farm tractors increased field speed, reduced fuel use, reduced soil compaction, and even allowed machines to be driven on hard surfaced roads. Invention of hydraulic lifts to raise and lower heavy two-row mounted corn pickers also was a major saver of human effort (Colbert, 2000).

By 1940, there were approximately 100 000 mechanical corn pickers operating in the US, with approximately 20% in Iowa, where approximately 50% of the corn was mechanically harvested. By 1948, US farmers owned approximately 300 000 mechanical corn pickers, with one-quarter of them in Iowa. By 1952, Iowa farmers owned approximately 110 000 mechanical corn pickers, and over 95% of their corn was harvested

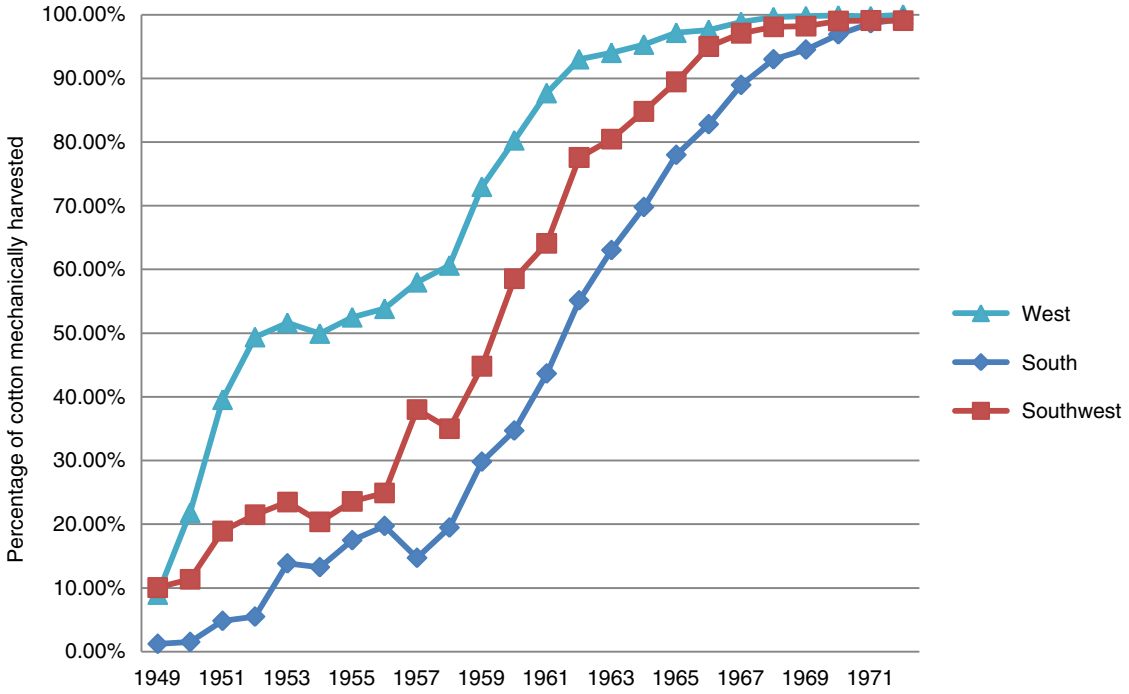

Figure 9 Percentage of cotton mechanically harvested by region, South, Southwest, and West, 1949–72. South includes Alabama, Arkansas, Georgia, Louisiana, Mississippi, Missouri, North Carolina, South Carolina, and Tennessee. Southwest includes Oklahoma and Texas. West includes Arizona, California, and New Mexico. US Department of Agriculture, Statistics on Cotton and Related Data, 1920–1972 (1974).

mechanically by that date (Colbert, 2000). Although the adoption of tractor-drawn or tractor-mounted corn pickers occurred over roughly 1940–60, many technical advances and improvements have occurred in mechanical corn pickers and combines since then. Today, almost all corn is harvested with a field combine that separates the corn kernels from the stalk, husks, and chaff. However, with a two-row mechanical corn picker of the early 1950s, a Midwestern farmer could harvest over 100 bushels of corn per hour.

Even larger changes came with the shift from hand to mechanical harvested cotton in the US South, which occurred starting in 1949 and largely ending by 1970 (Street, 1957; Meier, 1969; Heinicke and Grove, 2005). Two different technologies for cotton production had evolved in the US: (1) labor intensive Southern plantation production with its origins in black slavery; and (2) Southwestern irrigated desert production using day-haul labor, linked to migrants such as the braceros, which were Mexican contract labor employed under the Mexican Farm Labor Program of 1942–64. Because irrigated cotton faced many fewer weed problems, a permanent supply of labor was not needed on cotton farms in the West, but was needed in the South. When slavery ended in the South in 1865, many slaves became small tenant sharecroppers and continued to produce and harvest cotton until the harvesting of cotton was mechanized. Cotton production in the Southern Plains States of Texas and Oklahoma faced conditions somewhat intermediate between the South and West.

Given many factors, including differences in the supply of harvest labor, mechanical cotton harvesters were adopted more rapidly in the Southwest than in the South. For example, in the West, the percentage of cotton that was machine harvested increased from 10% to 50% in 4 years. In Texas and Oklahoma the increase was from 10% to 23% in the same time period. However, in the South, it took 7 years for mechanical harvesting to increase from 1% to 20%. More rapid adoption in the South did not occur until the 1957–64 period, when the percentage of machine harvested cotton rose from 10 to 65% (in the Southwest the increase was from 35% to 85%). Over this same time period in the West, the percentage of machine harvested cotton rose from 60% to 96% (Heinicke and Grove, 2005; see **Figure 9**).

In the production of processed tomatoes in California, all were hand harvested before 1965 – a hard, hot summer job. Research and invention to mechanize harvesting of processing tomatoes in California (CA) was spurred by the anticipated end of the Bracero Program in 1964. In the 1950s, 5.3 h of harvesting labor were required per ton of processed tomatoes. In 1950, Hanna from the department of Vegetable Crops, and Lorenzen, from the department of Agricultural Engineering, both at University of California-Davis (UC Davis), started to develop a system for mechanically harvesting processing tomatoes. Hanna started breeding a tomato that could withstand the stress of mechanical handling, would ripen uniformly and would detach from the plant during machine harvesting. Lorenzen worked on a machine that cut the plant at soil level and lifted it to a shaking mechanism. In the late 1950s, another UC Davis agricultural engineer developed a fruit-vine separator for Lorenzen's machine. By 1960, the University of California had obtained a patent for the new

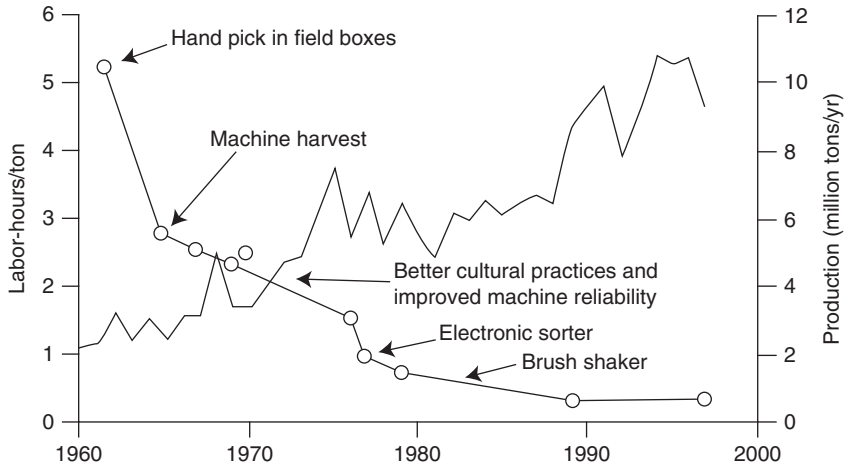

Figure 10 Typical harvest labor use and annual production of processing tomatoes: California, 1960–97. Reproduced from Thompson, J.F., Blank, S.C., 2000. Harvest mechanization helps agriculture remain competitive. California Agriculture 54 (3), 51–55.

tomato variety, and the Blackwelder Manufacturing Company undertook manufacturing and selling the first mechanical tomato harvesters.

This early mechanical tomato harvester cut the tomato plants at soil level and lifted them up into a shaking mechanism or separator that separated the fruit from the vines. Twelve workers rode on the early machines to sort the fruit, remove green or blemished tomatoes and clods of dirt, requiring 2.9 h of harvesting labor per ton of fruit, or a 60% reduction from hand harvesting. The tomatoes were conveyed directly into pallet bins that were transported on a trailer pulled beside the harvester (Thompson and Blank, 2000).

In 1964, 75 harvesters were sold in California, and in 1965, 250 were sold, yielding a combined capacity to harvest roughly 25% of the tomato crop. By 1969, 95% of the CA processing tomato crop was harvested by machine, at major social gain (Schmitz and Seckler, 1970). In the mid-1970s, a further major technical advance occurred with the invention of high-speed electronic color sorters, which identified and used blasts of air to separate ripe fruit from green and rotten fruit and clumps of dirt. With improved leveling and ridging of tomato fields, new tomato varieties and a new brush shaker innovation, labor requirements were reduced from 12 to 2–4 hand sorters per machine or to 0.4 h per ton (**Figure 10**). See **Figure 11** for a working Johnson mechanical tomato harvester. Over 35 years, this dominant CA technology has reduced labor requirements per ton of CA processing tomatoes by 92%, but this was not without major migrant farm labor issues (Schmitz and Seckler, 1970).

Current models of the Johnson self-propelled tomato harvester sold by the CA Tomato Machinery Company are equipped with two, 32-channel high-speed color and dirt sorters, use 2–4 hand sorters, and cost roughly US$450 000 (in 2010 dollars), with a life of 15–20 years under intensive postharvest maintenance. They have a maximum capacity of 70 ton h^{-1} and are regularly operated in two, 10 h shifts. Total harvesting costs are approximately US$28 per ton in 2010 prices. Under this new technology for California processing tomatoes, yield per acre and total production have increased

Figure 11 Self-propelled Johnson Mechanical Tomato Harvester (ca. 2010). Courtesy of California Tomato Machinery.

from 3 million tons (69% of total US tonnage) in 1965 to approximately 12 million tons in 2010 (96% of total US tonnage). (In the 1960s, US production of processed tomatoes was divided among three areas: California, the Eastern states of New Jersey, Delaware, Maryland, Pennsylvania, Virginia and New York; and the Midwestern states of Indiana, Illinois, Ohio and Minnesota. Now only 4% of production is outside of California.)

Substitution of Biological Advances and Chemicals for Farm Labor and Other Agricultural Materials

Field crop improvement has been the result of organized public research and innovative genetic improvement by private seedsmen and seed companies, and farmers' improvements in cultural and management practices. One of the great success stories of US agricultural research and development is the contribution of enhanced genetic potential to grain yields in major field crops. The rapid gains for corn started in 1930, for soybeans in 1940, and for wheat after 1954. The research work that underlies these genetic advances was largely undertaken in the public sector during the first half of the twentieth century. The scientific discovery of hybrid corn varieties for the

Corn Belt was the result of cooperative research undertaken between agricultural experiment stations and the USDA. Reproduction and sale of these early hybrids, which became available to farmers in the late 1920s (Griliches, 1960), were left to the private sector. For example, Pioneer raised its first commercial hybrid seed corn in 1925 and sold its first in 1926.

After the initial round of hybrid corn adoption, the same principles were applied to develop a sequence of new hybrids, with each new generation of hybrids producing some superior characteristics and replacing existing lines. Moreover, in the 1960s, corn breeders moved to single-cross hybrids to obtain higher yielding corn varieties. Over 1925–75, private seed corn companies used mostly public sector (state agricultural experiment stations of the Midwest and USDA) developed inbred lines in their double-cross corn varieties sold commercially. This, however, began to change c. 1970, and by 1984, the private sector was largely developing its own inbred lines used in commercially successful hybrid corn varieties for Midwestern farmers (Huffman and Evenson, 1993, pp. 155–162).

Soybeans became an important oilseed and meal source in the 1950s. Although early genetic improvement came from genes of imported varieties, a successful public soybean improvement program emerged in the US by the late 1960s (Huffman and Evenson, 1993, pp. 162–167). In these early years, farmers purchased seed beans from other farmers or from private seed companies and planted them. They frequently saved their own seed and planted it, but as genetic resistance to pests eroded, farmers sought out new bean seed. The USDA and later the state agricultural experiment stations were involved in the early development of soybean varieties that were adapted to the Midwest.

The soybean is self-pollinated and extremely photoperiod sensitive. In self-pollinated crops, it is difficult to create hybrids and easy for farmers to save and plant their own seed, and photoperiod sensitivity means that each soybean variety will perform well in only a small geo-climatic area.

In the 1960s and 1970s, farmers were using crop rotation, mechanical cultivation, and hand weeding to control weeds, which can dwarf soybeans.

Starting in the mid-1960s private sector soybean breeding emerged, and the relative importance of private sector developed soybean varieties grew after the passage of the 1970 Plant Variety Protection Act, and the 1985 *ex parte* Hibberd court decision. With this act, the private sector had stronger property rights to their new varieties (Huffman and Evenson, 1993, pp. 162–167). By 1990, the private sector had become the dominant source of new soybean varieties for Midwestern farmers.

Early successful wheat varieties were imports, largely from Europe. By 1949, public sector research activity had become a source of successful wheat varieties for farmers in the Great Plains and Midwest. Wheat is also a self-pollinated crop, and farmers can successfully save part of their harvest for next years' seed. Historically, yield improvement has been slow (Huffman, 2009). Hence, even with the 1970 Plant Variety Protection Act, the private sector did not find wheat varietal development to be a long-term profitable activity. This left new varietal development largely to the public sector. For the Corn Belt States, soft red winter varieties are most frequently planted by farmers, and for Minnesota, hard red spring and durum wheat varieties are most frequently planted (Huffman and Evenson, 1993, pp. 167–177).

Private sector development and the sale of commercial pesticides to farmers, starting in the 1940s and accelerating in the 1970s, provided a less labor and machinery intensive method for controlling plant pests. In 1999, US expenditures on insecticides were $3 billion or 33% of the world market. Forty-five percent of the insecticides applied were devoted to the agricultural sector. Although insecticides were initially hailed as a miraculous method to eliminate pest problems, the widespread use of any particular insecticide results in the development of tolerance by the target pests (Zilberman, 2004), high rates of insecticide application, and low effectiveness of these chemicals. In addition, high rates of application of insecticides have frequently caused environmental and human damage (Fernandez-Cornejo, 2008; NRC (National Research Council, Committee on the Impact of Biotechnology on Farm-Level Economics and Sustainability), 2010).

In the US, the use of herbicides or weedkillers in agriculture increased dramatically after the 1950s; herbicide use is now greater than the combined use of insecticides and fungicides. Plants exhibit varying levels of tolerance to herbicides. Some plants are highly sensitive and can be damaged or killed by very low doses of certain herbicides, whereas plants that have a high tolerance can be unaffected by herbicides that kill other plants. Hence, farmers have used private sector developed herbicides to selectively control weeds in field crops for more than 40 years.

The discovery of DNA in 1953 and a gene splicing technique in 1973 set the stage for genetic engineering of new field crop varieties for herbicide tolerance (HT) and insect resistance (IR) in the 1990s.

One major pest experienced by Midwestern farmers is the European corn borer, which damages stocks and makes the corn plant subject to lodging. *Bacillus thuringiensis* is a bacteria that occurs naturally in the soil. Several advantages exist for *B. thuringiensis* corn varieties. (*B. thuringiensis* produces spores that form the crystal protein insecticide δ-endotoxins. The protein toxin is active against species of the order Lepidoptera, Diptera, Coleoptera, Hymenoptra, and nematodes. When these insects ingest toxin laden crystals, chemicals in their digestive track activate the toxin. It inserts into the insect's gut cell-membrane, and dissolves, and eventually causes death of the insect.) First, the level of toxin expressed can be very high, thus delivering a lethal dosage to target insects. Second, the corn plant produces the toxin throughout its life and the toxin is expressed relatively uniformly throughout all plant parts. Hence, *B. thuringiensis* provides season-long protection against target insects, but has no significant effect on other insects. Third, the toxin expression can be modulated by using tissue-specific promoters, and fourth, GM resistance replaces the use of synthetic pesticides in an attempt to kill target insects. Fourth, the *B. thuringiensis* toxin expressed in the corn plants is not toxic to humans or animals. Although the early *B. thuringiensis* corn varieties were resistant to the European corn borer, they were also somewhat protective against the corn earworm, the southwestern corn borer, and to a lesser extent, the cornstalk borer (Fernandez-Cornejo and McBride, 2002). Later, *B. thuringiensis*-corn varieties also carried resistance to

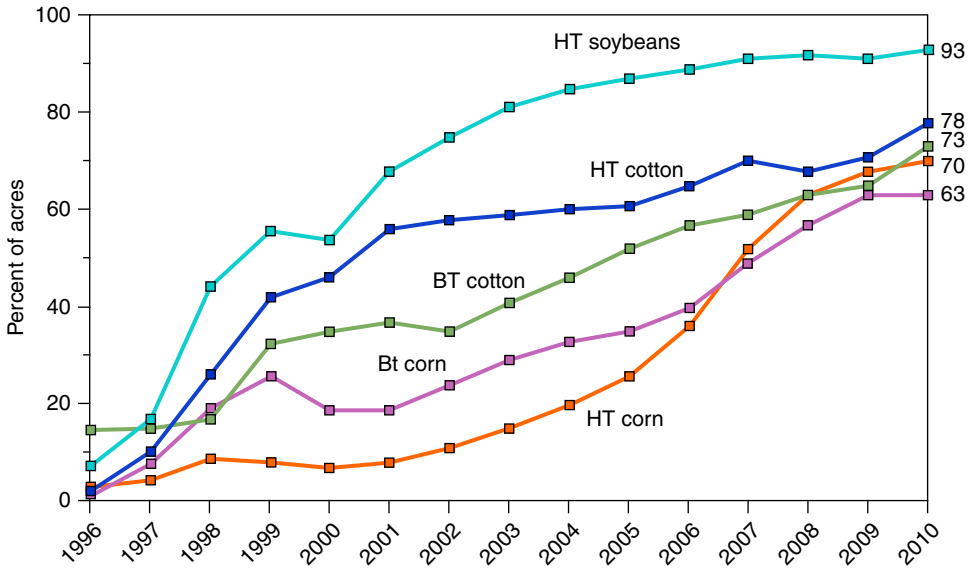
corn rootworms, which are a pest that reduces and weakens the root structure of corn plants. New evidence shows that farmers planting nonGM corn hybrids are major beneficiaries from other farmers planting *B. thuringiensis*-corn hybrids because area-wide moth counts have been steadily declining as the *B. thuringiensis*-corn adoption rate in an area increases (Hutchinson *et al.*, 2010). However, some evidence of resistance to GM rootworm control is surfacing (NRC (National Research Council, Committee on the Impact of Biotechnology on Farm-Level Economics and Sustainability), 2010).

Some farm crops have also been engineered for HT. For example, one crop variety is resistant to a particular commercial herbicide – largely Monsanto's Roundup, which contains the active ingredient glyphosate. HT has been introduced into US commercial soybean, corn, cotton, and canola varieties. With Roundup Ready soybean varieties, farmers plant the HT variety and roughly one month after emergence of the crop and accompanying weeds they apply Roundup, which kills all of the plants in the field except for the Roundup Ready Soybean plants. This then leaves the treated soybean fields largely free of weeds. Moreover, the effectiveness of applying the herbicide Roundup to Roundup Ready soybean plants is not sensitive to modest deviations in the application date, which is a major advantage to farmers that have off-farm jobs, other competing uses for their time, or who face uncertain (rainy) weather conditions. However, localized problems with weed tolerance to glyphosate have occurred (Fernandez-Cornejo, 2008; NRC (National Research Council, Committee on the Impact of Biotechnology on Farm-Level Economics and Sustainability), 2010).

Although there have been periodic claims that GM wheat varieties will soon be available to US farmers, this has not occurred. GM wheat varieties with HT have been tested, and GM resistance to the fungus Fusarium, which degrades grain quality, could also benefit growers (Wilson *et al.*, 2003). However, a large share of US wheat is exported, and the current opposition of Europe, Japan, Korea, and some other Asian countries to GM products continues. With this political resistance, general US introduction of GM wheat could significantly reduce export demand for US wheat (Taylor *et al.*, 2003). Although a two-tiered handing, storage, and marketing system where GM and nonGM wheat are separated might be acceptable to importers of US wheat, this system would be costly to operate, and there remains major concern about adventitious comingling of GM and nonGM wheat crops (Wilson *et al.*, 2003). Hence, the successful development of a GM wheat market is still in progress. One broad implication is that low investment in general genetic improvement of wheat and a lack of GM wheat varieties tolerant to herbicides have undoubtedly been a factor behind wheat losing its competitiveness with corn and soybeans in Midwestern states.

A recent National Research Council (NRC) report (NRC (National Research Council, Committee on the Impact of Biotechnology on Farm-Level Economics and Sustainability), 2010) summarizes the generally favorable environmental effects of these GM crop varieties. However, when US farmers purchase GM soybeans, they must sign an agreement with the seed company waving their right to save GM seed for their own use or for sale. Ht corn has many of the same advantages, although corn is naturally more weed resistant than soybeans. The herbicide Atrazine can be used on nonGM corn to control broadleaf weeds. However, Atrazine use has contaminated ground water in the Midwest, and consumption of this polluted water is alleged to be associated with birth defects, some forms of cancer and other health problems that the Environmental Protection Agency is continuing to review.

In 1995, no significant acreage of US crops was planted to biotech crop varieties, and in 1996, the rate of adoption was low, being higher for *B. thuringiensis* cotton and Ht soybeans than for Ht corn and cotton or *B. thuringiensis* corn (**Figure 12**). *Bacillus thuringiensis* cotton has been adopted in some areas of the South, but not in other areas where insect problems, including tolerance to chemical insecticides, were less severe. The HT cotton adoption rate surpassed *B. thuringiensis* cotton adoption by 1998, reflecting the fact that weeds are a persistent problem in cotton relative to insect pests, and Ht cotton has experienced higher adoption rates than *B. thuringiensis* cotton through 2010.



In sum, these new biological controls of crop pests provide important and effective substitutes for farm labor, machinery, and insecticides.

More on Mechanization of Fruit and Vegetable Harvesting

Although the most storied success in mechanical fruit and vegetable harvesters is the self-propelled tomato harvester in California, mechanical harvesters are being used by growers to harvest tomatoes in the Eastern Corn Belt, and other fruits and vegetables for processing in California, Florida, Arizona, the Upper Midwest, and New England. In the Midwest and Eastern processed tomatoes, the Pik Rite Company is a leader for inventing and manufacturing tractor-drawn harvesters for small-scale fruit and vegetable harvesting. Pik Rite's first mechanical tomato harvester was built in 1983, and sales began in 1986 after 3 years of improving and testing.

The Model 190 is a low capacity, 30–40 ton h^{-1}, harvesting machine with a lateral rotating single-brush-shaker system (**Figure 13**). (The model HC 290 is a high capacity, 70–80 ton h^{-1}, harvesting machine with a dual lateral brush-shaker system.) This machine has high-speed optical color sorters with blasts of air that aid separating ripe tomatoes, unripe tomatoes, and chunks of dirt. The cost of this machine is US$150 000–US$160 000 in 2010 prices, and has a work life of 12–15 years, but harvesting costs in the Midwest are substantially higher than in California, roughly US$48 per ton (in 2010 prices). The Pik Rite tomato harvester is in use in Indiana, Michigan, Ohio, and Pennsylvania.

In Midwest- and Eastern-grown cucumber, carrot, and pepper production, Pik Rite also develops and markets tractor-drawn mechanical harvesters for processing cucumbers, carrots, and peppers. The cucumber harvester has a special dirt removal system that uses blasts of air along with a 'scrubber' belt to remove trash (see **Figure 14**). It also has nonpinch conveyor chains, spaced so that small- and medium-sized cucumbers are saved and elevated to a storage bin, but oversized fruit exit with the vines into the field for better harvesting efficiency. This separation process is aided by blasts of air

Data for each crop category include varieties with both HT and Bt (stacked) traits.
Sources: 1996–1999 data are from Fernandez–Cornejo and McBride (2002). Data for 2000–10 are available in the ERS data product, Adoption of genetically engineered crops in the U.S., tables 1–3

Figure 12 Rapid growth in adoption of genetically engineered crops continues in the US.

blowing the vines, and chaff upward and out of the rear of the machine. This machine can unload 125 bushels in 20 s.

In Florida orange and orange juice production, historically the trees were hand-picked by workers on ladders with a bag, and when the bags were filled, the worker transferred the fruit to a large metal box on the ground. Several companies, for example, Coe-Collier, OXBO, and Korvan, manufacture and sell tree fruit harvesters to Florida orange growers. These machines are basically of two types. One type is a shake-and-catch system consisting of a two-part self-propelled unit, with the main power unit grasping the trunk of the tree. The second part of the harvester moves along the opposite side of the tree with a system to collect, store, and convey the fruit into a truck to be transported to a semitrailer at the edge of the grove. The two units lock together around the trunk (or limb), and both have a slopping to the middle catchment rail system, for example, see the Coe-Collier trunk shaker and receiver in Figure 15.

The power unit shakes the trunk (or limb) of the tree, and this hopefully dislodges the fruit so that it falls on the catchment rails, rolls to the middle, and is conveyed into a truck. The stems of citrus fruit are tightly attached to the tree limbs, and this type of citrus harvesting machine shakes the trunk vigorously to generate enough force to dislodge fruit. The severity of this shaking can seriously damage the bark on the orange trees, and orange growers in Florida are not currently using the shake-and-catch harvester. However, a very similar harvester is used for California processing plums, where the ripe fruit detach more easily.

Figure 15 Coe-Collier self-propelled trunk shaker and receiver for mechanical harvesting Florida processing oranges (ca. 2010). Reproduced from Futch, S.H., Roka, F.M., 2004. Trunk shaker mechanical harvesting system. Citrus Industry 85 (7), 20–21, with permission from University of Florida, IFAS Extension.

The second type of mechanical harvester for processing oranges is the bat-shaker system. With this system, a tractor-drawn machine containing rotating bats is pulled alongside a row of trees containing ripe fruit. The rotating bats then dislodge the fruit, and they fall to the ground. The fruit is then picked up by hand labor or rakes, and windrow machines gather and collect them. OXBO also makes a tree canopy-shaker with a catching table. Only the self-propelled shake-and-catch system is being used by Florida orange growers (Calvin and Martin, 2010).

Because oranges remain firmly attached to the tree, even when ripe, they are difficult to dislodge. This has hindered the development of mechanical harvesters. The University of Florida (U FL) has experimented with fruit-loosening agents, such as abscission. When applied, this chemical loosens the stems so the ripe fruit is more easily dislodged, which reduces damage from mechanical harvesting. However, mechanical harvesting of Valencia oranges poses an additional problem in that there are two seasons of fruit at harvest time: (1) mature fruit ready for harvest, and (2) young crop of oranges intended for the next year's harvest. A successful abscission chemical is applied to selectively loosen the mature fruit, leaving the young crop unaffected. Overall, because of potential tree damage, tightly clinging fruit, and two-crops on one tree at the same time, mechanical harvesting of FL oranges for processing has a low adoption rate (6–12%) (Roka, personal communication, 2010).

Mechanical harvesters have also replaced hand harvesters in the production of tart cherries in Michigan. These machines are of a shake-and-catch type, similar to the Coe-Collier FL orange harvesting machine though much lighter (see Figure 16). This machine is a two-part self-propelled unit where the catching table continuously moves harvested fruit to bins. Ripe tart cherries bruise some in this harvesting system, but because the cherries are going immediately for processing, the damage has not been viewed as significant. A large share of Michigan sour cherries are now harvested using this technology.

Figure 16 Self-propelled mechanical sour cherry harvester: shake, catch, and convey method (ca. 2010).

Figure 17 Korvan Co. self-propelled mechanical (wine) grape harvester (ca. 2010). Courtesy of Oxbo.

At one time, all California wine grapes were hand harvested, but growing international competition in the wine market has induced major cost savings, except in high-end wines. Currently, a large share of CA wine grapes is mechanically harvested. These machines are relatively tall, self-propelled units that straddle the trellised grapevine rows. The harvester has rotating arms that dislodge the fruit, which is then caught on a table and conveyed into a wagon. See the Korvan machine (Figure 17).

All strawberries continue to be hand harvested because, they are quite delicate and mainly harvested for the fresh market. Although other berries were traditionally hand harvested, the Korvan Company manufactures and sells a mechanical berry picker for processing berries (largely for raspberries and blueberries). This machine is self-propelled and surrounds the row of berry bushes similar to the wine grape harvester (Figure 18). This machine does some damage to the fruit, but because it is going immediately for processing, this is not generally viewed a serious problem.

A little experimentation has been done with robotic harvesters that use GPS to scout fruit locations and then pick the fruit. However, electronic assessment of tree fruit is

Figure 18 Korvan Co. self-propelled mechanical bush-berry picker: raspberries, blackberries, and blueberries (ca. 2010). Courtesy of Oxbo.

Figure 19 Self-propelled straight-through mechanical potato harvester (ca. 2010). (http://www.potatoharvesterusa.com/html/straight_thru_harvester.html; www.advancedFarmEquipment@Lenco-harvesters.com).

Figure 20 Washington State University and the USDA-ARS self-propelled mechanical fresh market apple (sweet cherry) harvester.

complicated by the fact that tree limbs and unripe fruit may block the view of the electronic 'eye' sensors.

As suggested above, advances in mechanical harvesting of fresh fruits and vegetables for the fresh market have progressed more slowly than for processed produce. However, the share of potatoes harvested for the fresh market has been and remains substantial, and the first mechanical harvesters were invented almost 100 years ago. Incremental innovations have transformed these machines into modern, self-propelled mechanical potato harvesters. Although simple mechanical potato diggers existed in the early 1900s, the first complete harvester-separator machines did not exist until the 1950s. Today, large-scale harvesting is done by a self-propelled machine that scoops up the potato plant and the soil beneath it. This material is elevated by a rotating apron-chain consisting of steel links several feet wide, which allows loose dirt to fall away, while retaining ripe potatoes. The chain deposits this mixture into an area where further separation occurs. Potatoes are then continuously elevated into a trailing wagon or truck. The most complex designs use vine choppers and shakers, electronic sorters and a blower system to separate good potatoes from rotten potatoes, stones, dirt, and vines (Figure 19). These are used for harvesting potatoes for the fresh and processing markets.

Other mechanical harvesters for fresh fruits and vegetables are largely experimental. Fresh market CA iceberg and organic lettuce, melons, strawberries, and tomatoes have substantial harvesting costs, and harvester-aids have reduced the workload. For example, the heads of iceberg lettuce are cut by hand and trimmed, then laid on a table that coveys them to the center, where workers on the field wrap them in plastic and place 32-heads per box, which are then stacked on the wagon. This process has significantly reduced the cost of harvesting and packing iceberg lettuce. A similar process is applied to melons and cantaloupes, with the slight distinction that they are packed directly into boxes without plastic wrap. Although the hand-harvesting cost of fresh market CA strawberries is very high, approximately US$615 per ton (in 2010 prices), this high-value delicate crop, which grows close to the ground and does not ripen uniformly, is currently impossible to mechanically harvest.

Washington State University and the US Department of Agriculture's Agricultural Research Service (USDA-ARS) scientists have developed a mechanical harvester for fresh market sweet cherries and apples (Peterson, 2005). A chemical fruit-loosening agent (abscission) is first applied to the trees a few days before harvesting. The mechanical harvester is a two-part, self-propelled machine, with each part going on opposite sides of the trees. Cushioned catcher pans on each unit are used to seal around the trunk and connect the two units. The harvester has a high density rubber arm on each unit that bumps the tree branches, and this energy dislodges the ripe fruit (see Figure 20). Both harvesting units have inclined catchment tables, but the mechanical conveyors are covered with a soft,

Figure 21 BEI International, Black Ice self-propelled harvester for delicate berries using air jests and padded walls and catchment areas (ca. 2010). Courtesy of BEI International.

spongy material that reduces impact, and the padded conveyers move the fruit gently to the outer top side of each of the machine catching tables. As the fruit rolls over the table, a fan blows away leaves and trash, and the fruit passes to two slowly rotating modest sized storage bins or boxes.

A benefit to growers and consumers is that mechanically harvested cherries have less bruising or damage than hand-harvested fruit and reduced exposure to bacteria-laden human hands. However, sweet cherry consumers are accustomed to their cherries having stems, but the mechanical harvested cherries are stemless. For mechanically harvested sweet cherries and apples, a special tree architecture is needed – short with a 'Y' shape, as opposed to the 20–25 feet tall conventional trees (see **Figure 20**). The mechanical sweet cherry harvester has excellent long-term potential for harvesting high-quality sweet cherries for the fresh market, at an 80–90% reduction in harvest labor costs, with less damage than hand-harvested cherries (Whiting, 2006).

The new BEI Black Ice Harvester works with delicate bush berries – raspberries, blackberries, and blueberries. The Black Ice Harvester uses jets of air to create a turbulent local environment within the machine and around the berries, which then gently dislodge those that are ripe. Between padded walls, the berries fall onto a bed or table (the Centipede Scale catching frame), and then are gently conveyed to one pound or smaller containers that are carried on the machine (**Figure 21**). A major advantage of this machine is that berries and bushes are not touched by a picking or rotating-arm mechanism. This helps minimize damage to ripe berries and scarring of the bushes. Given the minimal plant damage from the harvester, the machine can be used to make multiple passes over the same bushes as the berries ripen at different dates. With this machine, quality meets or exceeds that of hand-harvested fruit, and because no human handling of the fruit is required in the harvesting and packing, there are reduced food safety concerns. The machine is currently being farm tested, and its estimated cost is US$150 000 (in 2010 prices) for the smaller rear-loading model and US$200 000 for a larger top-loading model.

Structure of Farms

The structure of US farming has changed steadily over time, particularly after the available free land from the Homestead Act ended in the 1890s. Advances in size have been primarily driven by long-term mechanization, later automation, and long-term rising real wage rates in nonfarm sector (Huffman, 1996). Other factors include the use of improved of crops and livestock, which have dramatically raised the productivity of land and labor.

Aggregate US farm output was 5.5 times larger in 1990 than in 1890, but the number of farms has declined from 4.5 million (after peaking at 6.4 million in 1910) to 1.9 million in 1990. Currently, there are approximately 1 million farms in the US. With the number of farms declining and aggregate farm output growing rapidly, average output per farm (in constant output prices), one plausible measure of farm size, grew rapidly. Using this measure, average farm size was 1.6 times larger in 1940 than in 1890, but was 8.8 times larger in 1990 than in 1940 (or 14 times larger than in 1890). Since 1960 US farms have become more specialized in their products, and the average number of products per farm has declined everywhere except perhaps in California, where there is an incredible array of crops produced – roughly 250 currently. Somewhat surprising is the fact that USDA data show that aggregate real inputs under the control of US farmers have hardly changed since 1900, but real output has been growing exponentially at 1.6% yearly. This is only possible when there are large increases in multifactor productivity (Huffman and Evenson, 2006).

Long-term trends in labor, land, buildings, farm machinery, and farm chemicals are less well-known (see **Figure 22** and data for 1910–95). These data show a sizeable decrease in the demand for farm labor, especially after 1950, and the changes are generally parallel to the reduction in the number of farms. At the same time, machinery and chemical (fertilizers and pesticides) input use increased, whereas land and buildings inputs remain largely unchanged over time. Thus, land and buildings inputs per farm have risen at approximately the same annual rate that farm numbers have declined. The positive trend in machinery input shows a major reversal in 1980, and declined through 1994 (see Huffman and Evenson, 2001).

Estimates of the Wage Elasticity of Demand for US Farm Labor

The economics of labor demand is more complex than its underlying simplistic theory, but it provides a conceptual framework on which empirical estimates of the wage elasticity of demand for labor can be obtained. Huffman and Evenson (1989) and Schuring *et al.* (2013) have extended this conceptual model to include multiple outputs (up to four) and multiple inputs (up to five). (These articles use a normalized quadratic profit function from which the multiple-output supply and

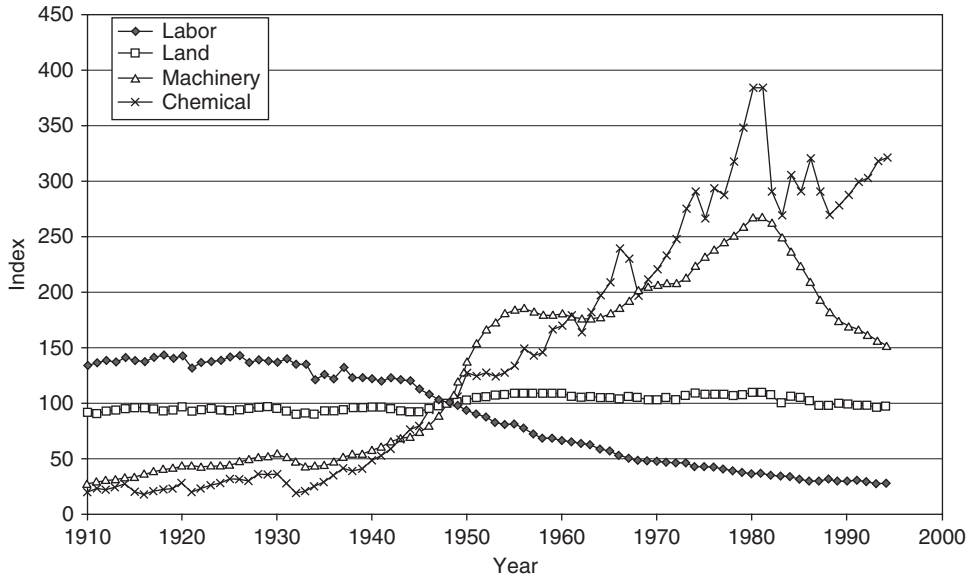

Figure 22 US aggregate usage of farm labor, land, machinery, and chemicals, 1910–94 (1948 = 100). Adapted from Huffman, W.E., Evenson, R., 1989. Supply and demand functions for multiproduct U.S. cash grain farms: Biases caused by research and other policies. American Journal of Agricultural Economics 71, 761–773.

Table 1 Output supply and input demand price elasticities: US cash grain farms, 42 states, data at 5-year intervals (1949–74)

Quantity	*Price elasticity with respect to normalized price of*						
	Fertilizer	*Fuel*	*Machinery*	*Labor*	*Wheat output*	*Soybean output*	*Feed grain output*
Inputs:							
Fertilizer	−1.203	0.237	0.334	0.278	−0.283	1.000	−0.364
Fuel	0.342	−0.717	0.690	−0.362	−0.370	0.370	0.278
Machinery	0.199	0.285	−0.606	0.464	−0.203	0.008	−0.147
Labor	0.130	−0.117	0.363	−0.508	−0.416	0.033	0.516
Outputs:							
Wheat	0.116	0.105	0.140	0.367	0.968	−1.051	−0.646
Soybeans	−0.852	−0.082	−0.011	−0.059	−2.178	1.313	1.871
Feed Grain	0.094	−0.050	0.064	−0.285	−0.404	0.565	0.016

Note: The elasticities in the last row and column are derived residually, others are estimates; all evaluated at the sample mean of the data.
Source: Reproduced from Huffman, W.E., Evenson, R., 1989. Supply and demand functions for multiproduct U.S. cash grain farms: Biases caused by research and other policies. American Journal of Agricultural Economics 71, 761–773.

input demand functions are derived. The C–D production function does not generalize to multiple-output technology in any meaningful way.) The first econometric study uses data on outputs, inputs, and prices of cash grain farms in 42 US states over 1949–74. Because the output and input quantity data were derived from the Census of Agriculture, observations are at 5-year intervals over this 25-year period.

Table 1 reports own-price elasticities of demand for inputs and supply for outputs by farms, which are evaluated at the sample mean of the data. They are the numbers on the diagonal in the table, for example, −1.203 in the first row and column represents the own-price elasticity of demand for fertilizer, or a 1% increase in its price causes a 1.2% decline in the quantity of fertilizer demanded by cash grain farmers over the sample period. Also, note that farm labor has the lowest own-price elasticity (i.e., smallest negative) of demand. The own-price elasticities of supply of outputs are positive, as expected, and large for soybean and wheat, but quite small for feed grains, which may be because of a restrictive government farm program on feed grain acreage during this era.

The off-diagonal elements are cross-price elasticities, for example, 0.237 at the top of the second column represents the 0.24% change in the quantity demanded of fertilizer, because of a 1% change in the price of fuel. The own-price elasticity of demand for farm labor is shown to be −0.51, or a 1% increase in the real wage reduces the demand for farm labor by 0.51%. A 1% increase in the price of machinery (fertilizer) increases the demand for labor by 0.36% (0.13%), but an increase in the price of fuel by 1% reduces the demand for fuel by 0.12%. These are largely as expected.

Table 2 Output supply and input demand elasticities: eight Midwestern states, annual data (1965–2004)[a]

Quantity	*Elasticity with respect to price of*								
	Soybean	*Corn*	*Wheat*	*Livestock*	*Farm capital*	*Farm labor*	*Farm energy*	*Farm chemical*	*Other farm materials*
Outputs:									
Soybean	0.110	−0.233	0.007	0.134	−0.093	−0.052	−0.008	0.078	0.056
Corn	−0.149	0.315	−0.052	0.208	−0.086	−0.041	−0.028	−0.110	−0.058
Wheat	0.055	−0.594	0.927	−0.706	0.047	0.274	−0.224	−0.277	0.040
Livestock	0.045	0.109	−0.032	−0.032	0.060	0.018	−0.002	−0.014	−0.152
Inputs:									
Farm capital[b]	0.073	0.106	−0.005	−0.140	−0.016	0.008	0.031	0.010	−0.067
Farm labor	0.022	0.028	−0.016	−0.023	0.004	−0.045	0.005	−0.009	0.035
Farm energy	0.028	0.152	0.108	0.022	0.137	0.038	−0.409	0.078	−0.154
Farm chemical	−0.122	0.269	0.059	0.067	0.021	−0.033	0.035	−0.667	0.370
Other materials	−0.019	0.030	0.002	0.153	−0.029	0.027	−0.015	0.080	−0.229

[a]The elasticities in the last row and column are derived residually, others are estimates; all evaluated at the sample mean.
[b]Farm machinery and breeding stock, but not farm land.
Source: Adapted from Schuring, J., Huffman, W.E., Fan, X., 2013. Aggregate Supply and Demand Functions for Midwestern U.S. Farms Under Rapid Technical Change. Ames, IA: Department of Economics, Iowa State University.

A change in the real wage also reduces the quantity of soybeans and feed grains supplied, but increases the quantity of wheat supplied, most likely because the latter is less labor intensive. Also, an increase in the real price of soybeans and feed grains increases the demand for farm labor, but an increase in the real price of wheat reduces the demand for farm labor. A number of other price elasticities may be of interest to some readers.

Schuring *et al.* (2013) use annual data on all farms of eight Midwestern states, 1965–2004, and in a similar study, **Table 2** reports estimates of the own- and cross-price elasticities of supply and demand, evaluated at the sample mean of the data. It shows that the own-price elasticity of demand for farm labor is −0.045, which is approximately one-tenth the size of the US cash-grain farm study. An increase in the wage for farm labor also reduces the demand for farm capital and chemicals, but increases the demand for farm capital (machinery and breeding stock) services, farm energy, and other materials. An increase in the real price of corn and soybeans increases the demand for farm labor, but an increase in the real price of wheat and livestock reduces it. A general interpretation of the other elasticities is similar.

These results show that one can obtain empirical estimates of the wage elasticity of demand for farm labor from aggregate data. However, the empirical results suggest that for cash grain farms and Midwestern farms, the wage elasticity of demand for labor is relatively small, or labor demand is wage inelastic. It is expected that the wage elasticity of demand for labor in the production of fruits and vegetables is somewhat larger because labor's cost share is much larger there than for wheat, feed grains, and Midwestern livestock.

Conclusions

With continued innovation in farm machinery, genetic improvement of crops and farm animals, and a return to rising real wage rates, we can safely predict that the quantity of labor used in US agriculture will continue to decline slowly and the number of farm workers will decline and farm size will continue to increase. Future mechanization of fruit and vegetable crops will be driven largely by benefit-cost considerations, including the likely future international competitiveness of the US industry. Relatively efficient machines exist for mechanically harvesting vegetables and fruits for the processing market. The most exciting finding is that there are new and effective harvesters that are in the final stages of testing for fresh market berries, apples, and sweet cherries. These technologies would move forward rapidly if there is a sudden increase in the cost of harvesting labor, or uncertainty of labor availability. Furthermore, these machines have potential for other crops. However, a short-term hurdle is that some crops are declining in planted acreage because of changing demand and international competition, and older tree and vine architectures are not compatible with newer harvesting systems. As it becomes more profitable for farmers to adopt this next generation of harvesting technology, orchards may increasingly be replaced with shorter and trellised trees and vines. Uniform ripening of fruit and berries is also critical to the success of these new harvesting systems (Huffman, 2012).

Glossary

Encomienda Grants of land that included rights to the labor of all residents on that land.
GlobalGAP International standard for good agricultural practices.
Guest workers Individuals invited (by receiving a limited visa) to work in a specific country for a specified time period.
Hacendado Owner of large land areas.
Hacienda A large land area.
Inelastic demand Demand that does not respond to changes in price.
Petrodollars Money generated by the sale of oil and natural gas.
Piece rate Work that is paid per unit produced or for specific task completed.
Reproduction of costs of labor What it takes to bear and raise a child, educate and train her, and provide for her health and well-being until she enters the labor force.
Undocumented Without legal status in the country where the individual resides. This status occurs when one overstays one's visa or enters without official endorsement.

Introduction

Women and girls have worked in agriculture since plants and animals were domesticated (Flora, 1985). Agricultural labor can be unpaid (such as on-farm family labor), paid-in-kind (such as barter or labor exchange), self-employed (such as marketing of one's own produce), or wage labor (World Bank, 2009). As a few accumulated land from the many, women work as comanagers, unpaid household labor, field hands, or in packing sheds. With the industrialization of family farms, women shifted from producers of agricultural goods to consumers (Barlett, 1993; Akyeampong and Fofack, 2012). Global production, distribution, and marketing systems are increasingly flexible and feminized (Bain, 2010, p. 343). This has increased the vulnerability of women farm workers, and at the same time it has increased the profitability of labor-intensive agricultural production. Women farm workers, who represent 20–30% of the approximately 450 million people employed worldwide as waged agricultural workers (the proportion is higher, at approximately 40%, in Latin America and in the Caribbean and parts of Africa), face specific difficulties (DeSchutter, 2012; Fontana *et al.*, 2010). Moreover, when all agricultural workers, paid and unpaid, are considered, women make up the majority of those workers.

History of Women as Agricultural Labor

Traditional communities were based on subsistence production with very little for sale. As these communities were penetrated by world markets, the division of labor in agriculture changed dramatically. In much of the colonized world, particularly Africa and Latin America, the first impact on traditional farming systems was the removal of male labor to work in seasonal plantation agriculture. Men were needed for the sugar and banana harvest. A few women followed to provide the necessary domestic functions of food and laundry. However, generally, women remained at home in charge of the subsistence production plots and animal production activities. Disruption of traditional farming systems intensified as harvests of export crops such as coffee and cotton utilized the entire families as laborers (Flora, 1988).

Integration into a world economic system changed land use – from subsistence crops and those destined for domestic markets to export crops. In much of Latin America, for example, large areas of very good land was given out as Spanish or Portuguese land grants and were farmed extensively with livestock, predominately cattle. Indigenous peoples and *mestizos* had use rights to land, on which they raised subsistence crops in exchange for the labor they provided to the *hacendado* (owner of extensive land holdings). These labor relations allowed the large landowners to access labor of the entire family at no monetary costs.

Hacienda agriculture involved appropriation of the and by the colonial power, who then deeded it to those who had provided the crown with enough wealth or conquest to justify their new landed status. The indigenous people on the land were part of the package in the *encomienda* system that paralleled the land granted by the crown. The peasants, now bound to the land by complex systems of legal and debt peonage, provided labor and received the use of a parcel of land for their own subsistence production, following the feudal land and labor relationships in Europe in the sixteenth century. *Hacienda* agriculture was much more self-contained than plantation agriculture, with little market orientation. Both male and female labor were often extremely cruelly used (Carrion, 1983).

Colonization in Africa and Asia followed similar patterns as the newly arrived Europeans established plantations of monoculture export crops, which needed seasonal labor. The institution of the 'hut tax' required cash payments and forced many farm households to sell their labor to the colonists on plantations or in the mines in order to escape imprisonment by the colonial power for nonpayment of taxes.

In attempts to rationalize and intensify production, particularly for export, colonial powers and nation states worked

hard to first privatize and then alienate land. In traditional agricultural communities, much land was controlled in common with village leaders assigning land use on a year-by-year basis. In this system, women had access to land through traditional land use rights. As land became titled and later sold, it was almost always titled in the name of the man in the household rather than the man and woman. The new private plots in the reformed areas and in new colonization and transmigration areas favored men's crops. There was seldom land left for the women's gardens, which were often vital for household nutrition and even survival (Lado, 1992). Women's collective production efforts were eliminated entirely. Often the animals that women would pasture, such as small ruminants, also were not allocated land for grazing. Women, thus 'freed' from production agriculture on their own land, were available for seasonal farm work on large estates and plantations.

The advent of capital-intensive export agriculture created a rural labor force totally dependent on sale of its labor. Many peasants lost their land use right, as a strategy of landowners to make sure peasants had no claim on the land. A relatively large rural labor force was thus available, forcing wages down, except for peak harvest periods. Women and men increasingly sold their labor for the same tasks, including the harvesting of coffee (a traditional source of temporary rural employment for women in peasant families) and cotton and for weeding and other cultivation tasks in row crops. Women again did the same agricultural work as men, this time for a wage as piece work, and were responsible for their household tasks.

Piece-rate pay is based on how much a task is completed, generally based on the number of baskets filled or the weight of the amount harvested. This is generally advantageous to the employer, as work becomes self-enforcing and requires much less supervision. Though the most efficient women may do well with this system of remuneration, it is often unfavorable to women in heavier tasks, where pay is calculated based on male productivity standards. Piece-rate pay encourages workers, especially women, to have their children in the field with them as helpers to perform the task faster (DeSchutter, 2012).

The year 1973 was a landmark for the developing countries, as events were set in motion that greatly affected the structure of agriculture around the world and the role of women within that structure (Flora, 1990). It was the year of the world oil crisis, with drastically increasing oil prices that dramatically shifted the terms of trade for most developing countries. In oil-purchasing countries with import substitution industries highly dependent on petroleum imports to run their factories, even more pressure was put on the export sector. More land went into export crops, even as prices dropped due to overproduction and inelastic demand. For the oil-producing countries, it meant increased indebtedness, with much of the borrowed money used to import food, as the subsistence agriculture sector, already relegated to women and virtually ignored, became even less viable. Suddenly there were lots of petrodollars recycle, and international banks competed to lend money (Flora, 1990). As inequality increased, more women entered the agricultural labor force. Deere and Leon de Leal (1982) show how in Latin America the sexual division of labor in agriculture declined, and yet wage differentials increased. In countries such as Ecuador, women were rarely employed as agricultural workers compared with men, and when they were employed received half the pay. They were most often employed as nonpaid family agricultural workers (Pontón and Pontón, 2008).

Women as Flexible Agricultural Labor: The Current Situation

While in the past plantations sometimes had a captive labor force which housed the entire families all year round and utilized all family members at times of peak labor demand, the emergence of factories in the field depended on a mobile labor market that appeared when labor was required. Those workers in fields and packing houses are hired on a temporary, part-time or contract basis and their wages and benefits are typically low (Allen and Sachs, 2007). With contracts, the grower has no legal responsibility to the workers, often resulting in lack of enforcement of the few labor laws that exist to protect agricultural workers (Standing, 1999).

As Pearson (2007) makes clear, labor markets are gendered institutions that reflect the socially constructed divisions of labor. In agricultural work, as in other sectors, women are in jobs that are temporary, part-time, and are considered low skilled. The majority of agricultural wage laborers in many countries, particularly women, either are working on land owned by spouses, families, or neighbors or are hired in informal markets. Most women working in agriculture thus typically do not have contracts that provide them direct control over the returns to their labor or that legally oblige employers to provide benefits or adhere to existing labor laws (World Bank, 2009).

Women are disproportionately represented in the 'periphery' part of the workforce that coexists with the 'core' segment of permanently employed farmworkers (FAO, 1998). The periphery segment of the farm labor market is generally paid on a piece-rate basis. This 'periphery' segment of the workforce is made of unskilled workers, often without a formal contract of employment, and their work is often seasonal or temporary (or classified as such even when it is in fact continuous). The main reason, according to DeSchutter (2011), that women are disproportionately represented in this segment is because they have fewer alternative options and are thus easier to exploit.

According to the World Bank (2009), women represent a larger proportion of laborers than men in the agricultural sectors of Asia, sub-Saharan Africa, and the Middle East and North Africa. Women also dominate in some Caribbean and Central American countries, especially in economies with low per capita income and increasing dependence on labor-intensive export agriculture.

Migrant Women Farmworkers

Migrant labor in agriculture is increasing, even as the agricultural labor force as a whole shrinks. Growth in agricultural employment has come in areas such as horticulture, floriculture, aquaculture, pigs, and poultry, in which factory-style operations are possible and economical. Economies of scale

apply, so the bulk of the work is carried out by paid employees (ODI, 2007). Women figure prominently in these sectors, such as shrimp-processing plants in Argentina, Bangladesh, India, and the Pacific Islands and poultry processing in Brazil. An increasing number of these industries employ labor under temporary conditions or through third parties.

Maintaining women in casual, informal employment and paying them less (or paying them through their male partners) are often justified through their roles in social reproduction (Raynolds, 2001).

Around the world, the globalization of fruits and vegetables has shifted agricultural work from men to men and women, with women seen as cheaper and more flexible workers for highly seasonal work (compared with plantations for bananas, palms, and other tropical crops) (Doss and SOFA Team, 2011). In many countries in Africa, Asia, and Latin America, women, who had not traditionally worked in agriculture on a salaried basis, are hired to harvest and pack the nontraditional export crops. They work long hours, often on a piece-rate basis and are not enrolled in social security or other benefits programs. They often do not have access to basic sanitary services. Usually hired as contractors, rather than direct hires, they have very little support in organizing collectively, even in countries such as Argentina with relatively strong labor laws.

Although fruits and vegetables in international value chains need contingent flexible labor that women tend to provide, the move from integrated peasant systems to plantations creates another type of women farmworkers. In Indonesia's palm-oil production, shifting land tenure from the community to the state, coupled with the family head (male) system of smallholder rights registration, has resulted in women as a type of plantation worker (White and White, 2012). Corporate land deals that basically expropriate communal land were granted in the 2004 Plantation Act through long-term land use concessions for 35 years and extendable for another 25 years. These concessions abolish customary rights (Raworth, 2004). Some plantations combine a nucleus estate with small holder production. However, often new smallholders are recruited from even poorer areas, displacing traditional farm families, or plots are allocated far from the farm household residence, creating conflict with the families who live there.

In many cases, the families do not receive the promised plots, and family members become plantation workers: contract workers (mainly male), casual workers for specific tasks (both male and female), and unpaid family members who assist the hired workers without pay or labor rights. These workers are primarily females and children. Spraying and fertilizing has become women's work, with substantial unprotected exposure to highly toxic chemical substances. Both hot weather and the fact that they must individually purchase safety equipment means that few women wear protective gear. At the same time, dependence on cash has increased, as monoculture had made both gathered foods and chicken raising impossible. Plantation work is typically piece rate, enhanced by more hands picking and packing. Women, especially, tend to be accompanied by children, male and female, in the fields (DeSchutter, 2011). Plantations depend on low-paid or unpaid family labor during seasonal peaks in labor demand. Women and girls, who still have their daily and often onerous household tasks, are an important part of this labor force.

The International Migration of Farmworkers

In richer countries, such as those in the European Union (EU), the US, Canada, Australia, New Zealand, Norway, Israel, the Russian Federation, South Korea, and the United Arab Emirates, where incomes have risen, the poor have become urbanized, and the rural poor are often aged or infirm, international migrants from poor areas in developing countries provide the bulk of the agricultural labor, both seasonal and year round. Although there have been some attempts to regularize such workers, many do not have legal documentation, which makes them particularly vulnerable to exploitation by employers, contractors, and smugglers and employers vulnerable to periodic raids and decimation of the productive workers through arrests and deportation. Thus many employers of agricultural workers are demanding immigration reform, either, as in the US, through comprehensive immigration reform (such as the National Milk Producers Association) or improved guest worker programs (Agricultural Workforce Coalition).

Guest Worker Programs

One way to get agricultural labor at minimum costs of the country in which the work is performed is through seasonal migrant labor, This allows the sending country and sending households to pay the reproductive costs of labor, whereas the employer only has to pay the labor costs, which, by recruiting many such workers, can be kept low. Countries such as the UK and Australia have instituted 'working holiday' programs to offset labor shortages in horticulture. Women often take advantage of such opportunities to be in the countries without sponsorship.

Some countries have institutionalized legal mechanism to recruit seasonable farmworkers. Women are increasingly part of this group in many countries. All low-skilled visa programs, which is how farm work is classified, must balance several potentially conflicting goals.

- Guarding against the exploitation of foreign workers.
- Maintaining appropriate wage and working conditions for domestic and foreign workers.
- Make the legal employment-based immigration system sufficiently attractive to employers to discourage illegal employment.

Many of the visa programs, such as that in Norway, require unskilled (agricultural) workers to be outside the country for at least 6 months before reentry. There are often quotas for agricultural workers. To receive the visa, the workers must already have an employer. These programs do not allow for family members to accompany the workers.

Some temporary visas for seasonal agricultural workers are based on government to government agreements, as in Canada, the Russian Federation, and South Korea. This can

provide more protection for agricultural workers, and uses sending country institutions for labor recruitment.

In the EU, guest worker programs have been facilitated by the entry of second tier countries into the common market, which means workers can cross borders without visas or specific labor contracts. Immigration is a shared competence between the EU and its 27 Member States. The EU has enacted legislation in the areas of visas, residence permits, family reunification, and illegal immigration, among others, but the EU Member States have the right to determine the number of admissions of third-country nationals in their territory for employment purposes, including temporary workers. The European Commission has adopted a proposal that would establish a fast-track procedure and a single residence/work permit for seasonal workers, including a multiseasonal permit. The EU has an agreement with Turkey regarding immigrants of Turkish origin (Library of Congress, 2013).

Guest workers programs have generally recruited males, but that is changing in such countries as Canada. The Seasonal Agricultural Worker Program (SWAP) in Canada is highly regulated to be sure that the migrants return home and presumably receive their labor rights.

There is little research done on migrant women entering male-dominated occupations, such as farm labor, and how that occupational migration flow is gendered. As women enter these highly masculinized programs, they face a number of problems that do not confront women working in the feminized part of the agricultural labor force (Preibisch and Encalada Grez, 2010). The women who qualify for the Canadian guest worker program (temporary visas) must come from rural areas and have experience as farmworkers. Yet they face disapprobation from their employers and their home communities for transgressing gender norms to migrate where their race, class and citizenship makes them exceedingly vulnerable. It is difficult for them to claim their rights under Canadian law.

In the US, immigrants were 4% of the farmers and farm labor force in 1970. By 2000, they were 22% of the farmers and farm labor force – primarily farmworkers. Mexican women were half as likely as Mexican men to be employed as agricultural workers, but they make up a substantial minority of the migrant agricultural labor force (Lowell *et al.*, 2006; Roenblum and Brick, 2011). Only 3% of unauthorized women work in agriculture, compared with 13% of unauthorized men (Capps *et al.*, 2013). The temporary agricultural worker program visa in place in 2013 – H-2A – is generally felt by farmers and farmworkers to be inadequate. The farmer must prove there are no green card or citizen workers available in the area, a procedure that can prove onerous. Then the farmer can recruit foreign workers, which is why many rely on labor contractors to get workers to the job as quickly as possible. Workers with H-2A visas are not eligible for permanent residency whereas they are in the US. Permanent visas for ongoing, nontemporary positions are heavily oversubscribed, and must be reapplied for each year to stay in-line.

Guest worker programs are a concern because they are costly and bureaucratic, consistently circumscribe workers' rights, and provide the wrong incentives to both workers and employers, resulting in the continued use of undocumented labor. Guest worker programs will not work for smaller farms, which are widely dispersed and have many different types of labor needs.

The undocumented network migration system has worked well both for agriculture as for other manually intensive industries in the United States. It is self-recruiting, self-transporting, and self-housing. It is the low-cost, market-based option, and the rational approach to eliminating undocumented labor would be to legalize this undocumented system itself, and allow the labor market, not the government, to allocate immigrant workers (Runsten *et al.*, 2013).

Key Gender Issues

Women worldwide combine their domestic responsibilities with their wage-earning activities. Lack of access to fuel and water in some rural areas, and lack of child care in other areas encourages women to take short-term agricultural work in order to continue their strenuous household obligations. Employers often refuse to hire pregnant workers, so women disguise their pregnancies in order to maintain their access to income.

Occupational segregation by gender within agriculture tends to justify paying women less than men. Bello Barros (1993) found strict gender divisions of labor in the apple industries of both Chile and Virginia, but that work that was male in one country was female in the other. In Chile, men pack the apples, whereas in Virginia women pack the apples. The high-value agricultural export industry is highly segmented and gender segregated (World Bank, 2009; Barrientos and Perrons, 1999). Dolan and Sorby (2003) cite vineyards in Northeast Brazil, fruit in Chile, flowers in Colombia and Mexico, horticulture in Kenya, vegetables in Sinaloa, Mexico, deciduous fruit in South Africa, and flowers in Uganda as employing more than 50% women in sex-segregated tasks.

Some tasks are 'feminized,' such as weeding on the farm, or poultry processing and flower packing in the factory, despite evidence of the ability of men to perform these tasks equally well in other companies or countries. The reverse also holds, and generally men run equipment and handle tools, jobs that usually require training, not a high level of strength, and elicit higher wages. Occupational gender segregation is particularly strong in some countries in South Asia, Southeast Asia, and Latin America (World Bank, 2009).

Stereotyping of gender roles is ubiquitous. For example, a manager in a cut-flower-processing plant in Kenya said that "women are more dexterous, which is good for flowers" (Collinson, 2001). This is mirrored in the cut-flower industry in Colombia and Ecuador (Korovkin, 2003; Lara, 1995; Medrano, 1996; Silva, 1996). Confining women to a limited number of occupations has high equity and efficiency costs, and it contributes to misallocation of labor and suboptimal investments in women's education because girls' potential is usually gauged through current market opportunities (Tzannatos, 1999).

Violence, Health, and Safety

The high prevalence of women in casual, low-paid employment with limited security leads to other abuses. Young

women from very poor areas become an increasing part of that migrant stream. Underage Khmer, Lao, and Myanmar girls migrate to work in agriculture in Thailand, where some are held captive working under poor conditions (Pearson *et al.*, 2006).

Violence and sexual harassment in the workplace are more frequent under these conditions. Men supervisors control decisions concerning work performance and hence remuneration for the 'task.' Studies have shown that women must trade sex for job security, markets, and other employment benefits that should be part of the labor contract. In studies of the cut-flower industry in Kenya, women reported that supervisors required sexual favors for job security, and refusal could lead to dismissal (Dolan *et al.*, 2002). This harassment occurs in spite of company codes of conduct that prohibit such behavior.

In India, despite the rise in agricultural workers wages that accompanied the Green Revolution from 1966 to 1988, women continued to receive substantially lower wages. Indeed the differential was greater in the Indian states with the highest increase in yields (Singh, 1996). Among the US farm workers, women are more vulnerable to exploitation than men, and they are paid even lower wages and given fewer benefits than their male family members (Kearney and Nagengast, 1989). The continuing vulnerability of female agricultural workers is demonstrated in a 2013 documentary aired on both PBS and Univision.

Women face health hazards in the cultivation of many crops reporting back pain and pelvic problems in rice cultivation and weeding. Agricultural work can be arduous for both sexes, but to the extent that women are concentrated in specific activities, they will experience greater exposure to some risks. Occupational safety risks can be high in factories and agro-processing plants, including equipment accidents, exposure to unsafe conditions, and contact with chemicals and toxic substances. Women who work in fish- and shrimp-processing experience arthritis and other negative health effects of standing or sitting in wet, cold environments for 10–12 h a day (USAID/GATE Project, 2006). In a recent study of the fish and shrimp industry in Argentina, the majority of the women interviewed held temporary jobs and therefore had no medical or social coverage. More than two-thirds of the women interviewed work more than 5 days a week, and 63% work more than 8 h a day (Josupeit, 2004).

The high value fruits and vegetables grown in monocultures require high rates of pesticide application. Although GlobalGAP's Labor Standards for Health and Safety offer some protection for full-time workers, particularly pesticide applicators, workers hired by contractors or part-time temporary workers are not necessarily included (Bain, 2010). These positions are generally held by women. They are subject to indirect exposure through pesticide drift at work and in their nearby homes (Harrison, 2011). Besides the dangers of pesticide drift, women pickers risk pesticide poisoning through residues on fruit and leaves as they are seldom provided with protective clothing and gear, particularly in developing countries. Pressures by retailers for cosmetic quality and low costs encourages hiring women as low cost, flexible, temporary subcontracted employees, for whom pesticide training and protective gear would be an extra cost in a tight-margin market. As employees of the contractor, the growers and their corporations have no direct responsibility for health and safety. Besides, in many countries, such workers are either undocumented or with employer-validated visas; there are huge penalties in terms of job loss and deportation for those who complain.

Health risks in the growing horticulture industry include exposure to toxic products through inadequate training and protective clothing, poor hygienic conditions, and physical demands and long hours. Every year at least 1 70 000 agricultural workers are killed as a result of workplace accidents, and some 40 000 of these are from exposure to pesticides (ILO, 2003). To the extent that women predominate in some of these activities, they have greater exposure.

Under conditions of temporary, seasonal, or limited contracts, no health insurance is provided. Where there are no on-site medical facilities, these women, in greater proportion than men, bear the cost of medical services. In factories or on plantations, such as in fruit-producing areas in South Africa, medical facilities may be few or lacking, and workers may even be dependent on employers for transport to medical facilities.

Potential for Improvements

The World Bank suggests that trade agreements include a gender analysis, examining the relative prices of factors that change demand for labor as sectors expand and contract; and extending legal rights frameworks for women agricultural laborers, including labor law and its implementation and enforcement. Unfortunately, those countries where women agricultural workers are most disadvantaged also tend to have the weakest labor rights enforcement mechanisms.

Even in countries where labor laws are seldom enforced, programs that help women agricultural workers become aware of their rights can strengthen the demand for labor law enforcement and reforms. Such education can strengthen local organizations of agricultural workers and help them be more inclusive of women as they negotiate with governments and with growers.

The disproportionate number of women in casual and seasonal jobs and the attendant risks for women and children increases the necessity to increase social protection for them (ILO, 2002). Social protection can focus on reducing risks or on maintaining assets. In the context of agricultural labor, social protection refers mainly to medical and unemployment benefits and pension provision. The extension of public social protection programs to temporary, casual, and seasonal laborers will address some of the issues of gender inequity in agricultural labor.

Unemployment insurance, health insurance, and pension programs are all inaccessible to temporary and casual workers in most developing countries and in some developed countries (FAO Legal Office, 2002). The private sector is unwilling to bear the full cost of these programs, so there must be an evaluation of the balance between private and social costs and benefits needs.

Labor contracts, particularly enforcing those of subcontracted workers, are particularly important. However without legal status in the country where they work, female

workers are unable to enforce contracts, even if they have them. A number of groups, such as Oxfam International, are working directly with major brands to ensure the enactment and enforcement of standards that take women and farm workers into account.

Improving Health, Security, and Safety

Providing a healthy workplace and maintaining the health of workers should be good business, but managers of companies may have to be convinced of the economic benefits of, or be forced into, applying basic standards. Health concerns for women include violence and sexual harassment in the workplace, exposure to human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS), as well as occupational safety issues surrounding, for example, accidents and exposure to unsafe conditions, chemicals, and substances. Overtime and night shifts can also create safety concerns for women, although these can also be used to restrict women from employment categories.

Improved information and data provided by laborers and labor organizations concerning a perceived problem can help lead to its resolution. Dissemination of policies is important, and the implementation of training programs is necessary. Worker organizations, supported by Non-Governmental Organizations (NGOs) are the most effective mechanism for such dissemination and education with the cooperation of employers. This is made more difficult when workers are subcontracted, as is increasingly the case.

The workplace is an extremely effective center for HIV and AIDS awareness campaigns. Plantations in Uganda were experiencing extremely high rates of mortality, but as government campaigns were complemented by company information and condom distribution, the mortality rate has fallen significantly. Human rights work in some regions has been expanded to domestic violence and its social and economic repercussions. Some companies have recognized the cost of violence and facilitated support for abused women (World Bank, 2009).

The ILO (2012) suggests that countries guarantee the equal treatment of part-time workers for social benefits, as is being done in many Organisation for Economic Co-operation and Development (OECD) countries. They also urge legal reforms to ensure formal equality, antidiscrimination laws and procedures, and equal tax treatment. However, such legislation to challenge gender stereotypes and confront discrimination are difficult to apply in the case of women agricultural workers, even in OECD countries.

Monitoring and Evaluation

Currently, there are few data on women agricultural workers, particularly those in flexible positions. Furthermore, that data are quite suspect, as often those who must cooperate to give data or access to the workers for sampling feel that such data might disadvantage them. In the US funding for the Survey of Agricultural Workers, conducted through the USDA is constantly under threat. Fiscal austerity gives cover for not knowing what is happening with the agricultural labor force. Data from 2012 state that only 18% of the 6 76 000 farm laborers and supervisors are female. Other key information has not been analyzed by gender. Almost three-quarters of hired crop farmworkers are not migrants, but are considered settled, meaning they work at a single location within 75 miles of their home. This number is up from 42% in 1996–98. Such proximity increases the possibilities of women becoming flexible farmworkers.

In other countries, the data are equally difficult to access, and probably equally threatening. Like in the US legal status of the worker or members of the worker household make it imperative that trust exists between the entity collecting the data and the employer, contractor, or worker. Less obtrusive data can be gathered from program records (numbers of farm operators trained in occupational health and safety issues), administrative records (incidence of occupational health and safety incidents and measures taken to prevent future incidents; number of women and men from district employed in agricultural enterprises annually), union records (percentage of women and men in activist or leadership positions), training records (number of women and men receiving training on labor standards and employment rights per quarter), government social security records (access of women and men to social security and unemployment insurance), legal authority records (change in number of cases of women and men accessing legal advice regarding legal rights), among others.

Subcontracting makes this all more difficult, as it is often unclear who the employer is and what obligations and responsibilities fall to which entity. In many countries, labor contractors remain unregulated and continue to operate with questionable legality. It is, however, a vicious circle for female agricultural workers, for without the number of workers it is difficult for auditors to verify the adequacy of standards that must be determined by the numbers, such as provision of toilets and adequate living quarters (Bain, 2010).

Conclusion

Although mechanization has decreased the number of farmworkers worldwide, women make up an increasing proportion of those who do farm work. They are more likely than men to be employed as flexible farm labor in intensive agricultural production, particularly horticulture, including the flower industry. The increasing use of contract labor and the lack of clear legal protections, particularly for immigrant farm workers, make women vulnerable to sexual and wage exploitation. Family responsibilities drive them into flexible farm labor increase their work load as they perform both domestic and paid labor.

Availability of affordable child care and transportation services to farmworkers increases the well-being of both mothers and children, as they must no longer choose between children in the field or left in a compound alone.

Around the world, women's groups are educating women agricultural workers about the legal rights as workers and encouraging them to demand them. These groups also provide support as women join together to demand their rights from labor contractors, employers, and the state. Increasing the ability of women agricultural workers to bargain collectively,

supported through effective policies and laws, would increase their ability to demand and receive equality of opportunity policies, equal pay for work of equal value, maternity leave and benefits, child care and reproductive health services. Preparing women for leadership roles in the male-dominated unions and following gender-equity guidelines increase union sensitivity to the gender implications apparently neutral issues for collective bargaining, including how wages are determined, leave, overtime, or bonus systems as these often in reality impact women and men differently (DeSchutter, 2012).

The ILO's mandate on gender equality is to promote equality between all women and men in the world of work. This mandate is grounded in International Labor Conventions of particular relevance to gender equality – especially the four key equality Conventions. These are the Discrimination (Employment and Occupation) Convention, 1958; Equal Remuneration Convention, 1951; Workers with Family Responsibilities Convention, 1981; and the Maternity Protection Convention, 2000. The mandate is also informed by Resolutions of the International Labor Conference – the highest level policymaking organ of the ILO – in 1975, 1985, 1991, and the June 2004 Resolution on Gender Equality, Pay Equity, and Maternity Protection.

Regularizing the access of agricultural workers, male and female, through a graduated visa program as proposed by Runsten *et al.* (2013) would go a long way to increasing the well-being of all women agricultural workers, as a legally divided workforce disadvantages both employers and workers and give women collectively an opportunity to address their shared issues around agricultural work.

Agricultural Labor: Labor Market Operation

P Martin, University of California, Davis, CA, USA

Introduction

Agriculture is full of paradoxes. Farmers are often praised as the independent yeomen who provide living links to the nation's founding fathers, yet agriculture receives more federal subsidies than many other US industries. There were too many farmers during the 1950s, when a million Americans a year moved to cities, whereas alleged shortages of farm workers were the rationale for importing almost 500 000 Mexican Braceros a year to work in the fields.

Thomas Jefferson, the third US President, believed that family farmers were the backbone of American democracy. Jefferson's phrase, engraved on the wall of a reading room in the Library of Congress, proclaims that "Those who labor in the earth are the chosen people of God." Jefferson believed that rural life was superior to urban life and a nation of self-sufficient family farmers who owned the land they farmed would guarantee respect for private property and preserve American democracy.

Family farms were the ideal as well as a widespread reality in 1790, when the first Census of Population found that 90% of the four million US residents lived in rural areas. The model farm included farmer, a large family, and perhaps a hired hand, usually a young man who lived with the farmer's family temporarily before becoming a farmer in his own right. Everyone on family farms worked to meet peak seasonal labor needs, explaining why school schedules were adjusted so that children were available when needed on the farm.

The fact that crops needed more workers during some seasons than others encouraged diversification to spread out the work and to make farm families self-sufficient. Most family farms in the early nineteenth century raised crops and tended livestock, and most did not generate a surplus to sell because there were few large US cities and European farmers produced similar crops. As technology increased the productivity of farmers, family farms got larger, producing a surplus to sell to urban residents in expanding US cities and abroad.

There were two other US farming systems that dealt very differently with the need for seasonal farm workers. In the southeastern states, plantations produced cotton and tobacco that were exported to northern Europe and other areas that could not grow these long-season crops. Slaves were bound to their plantations, ensuring that seasonal workers were available when needed. Slaves were eventually replaced by sharecroppers who lived and worked on small plots of what had been plantation land, and in the twentieth century, mechanization reduced the need for seasonal workers on cotton farms, although tobacco farms continued to rely on foreign-born farm workers.

The western US states had large landholdings often assembled by entrepreneurs who grazed cattle or raised wheat in the mid-nineteenth century. The transcontinental railroad, irrigation, and other changes made it profitable to switch to labor-intensive commodities in the 1870s. Large landowners expected to sell small plots of land to the family farmers who arrived by train, because it was assumed that large farm families were necessary to provide seasonal workers needed for fruit farming. However, a seasonal workforce was available with the Chinese workers who were imported to build the railroad and driven out of cities by discrimination. Farmers hired the Chinese to fill seasonal jobs, and waves of migrants with few alternatives to seasonal farm work followed, including the Japanese, Filipinos, Mexicans, and Dust Bowl Okies and Arkies in the 1930s.

This article summarizes the operation of the farm labor market, focusing on the unique ways in which agriculture handles the 3-R functions of all labor markets – recruitment, remuneration, and retention. It also reviews the Bracero and H-2A programs that provide farmers with legal guest workers and the efforts of unions to organize farm workers and bargain for wage and labor market changes. The farm labor market has always been different from other labor markets, and farm–nonfarm labor market differences still persist in the twenty-first century.

Farm Labor Market

All labor markets perform three essential functions that can be summarized in words that begin with R: recruitment, remuneration, and retention. Recruitment deals with matching workers and jobs, remuneration with motivating workers to perform by offering them wages, and retention with keeping the best workers and ensuring that sufficient workers will be available to fill seasonal jobs.

Agriculture deals with each of these R-functions in unique ways. For example, farm workers are often recruited in crews of 20–40 via intermediaries such as farm labor contractors, whereas nonfarm employers are more likely to recruit individual workers and screen them with written applications and interviews. Most US jobs pay hourly or monthly wages, whereas a significant share of farm jobs, especially seasonal jobs harvesting fruits and vegetables, pay piece-rate wages such as US$20 to pick a 1000 pound bin of apples, that is, worker earnings reflect productivity at the employer-set piece rate. Few farm employers have formal systems to identify the best workers or job-related benefit systems that aim to retain them. Instead, farm employers have more often worked together to ensure that sufficient seasonal workers will be available for all farmers when such workers are needed.

Recruitment and Contractors

Recruitment matches workers with jobs. In agriculture, where large numbers of workers are required to fill seasonal jobs, the most efficient recruitment mechanism is a central clearinghouse that allows farmers to list their job vacancies and workers to seek seasonal jobs that maximize their earnings and

minimize their unemployment and commuting time. Such clearinghouses can be operated by (groups of) employers, unions via hiring halls, or the public Employment Service, whose offices are now known as One Stops (www.careeronestop.org).

The logic of a central clearinghouse to minimize uncertainty for growers and unemployment for workers is clear, but there are few examples of their successful operation. Between the 1930s and 1960s, the US Department of Labor (DOL) operated a Farm Placement Service (FPS), which involved government agents taking job orders from farmers and helping migrant and seasonal workers to find jobs (Goldfarb, 1981). Some farm employers formed associations that acted as clearinghouses for seasonal jobs and workers, and some of these employer associations became labor contractors that moved workers from one member's farm to another.

Farm worker groups sued the US DOL in the 1960s, alleging that the FPS discriminated against farm workers by sending farm workers only to farm jobs, rather than providing them access to the full range of farm and nonfarm jobs at the Employment Service, including training services. In a 1973 settlement of the NAACP versus Brennan suit known as the Richey Court Order, DOL agreed to provide farm workers the same services that it provided to other workers, and the FPS was dismantled (Goldfarb, 1981). The public Employment Service today makes very few worker–job matches in US agriculture.

The employer associations that served as clearinghouses for workers and jobs also curtailed their activities, especially in California, as unions spread in the 1970s. The Coastal Growers Association (CGA), organized as a labor contractor in 1961 to pick lemons in Ventura County, CA, USA, provides an example. CGA's professional managers were able to reduce the number of pickers from more than 8500 to 1300 within a decade, demonstrating the inefficiencies that had crept into the farm labor system when the availability of Braceros held down wages (Mamer and Rosedale, 1980). The average earnings of these fewer workers rose to twice the minimum wage, and CGA provided job-related benefits such as health insurance, paid vacations, and subsidized housing that were rare for seasonal farm workers.

The win–win benefits of applying modern human resource policies to seasonal farm workers spread in California, Florida, and other major producers of fruits and vegetables during the 1970s, so that most agribusinesses had a personnel manager and employee handbook by the early 1980s. However, workers at CGA and many of the other associations voted for union representation, in part because personnel managers coming to agriculture from nonfarm firms were familiar with unions and did not oppose them as strongly as growers who hired workers directly. When the United Farm Workers (UFW) union went on strike in support of demands for significant wage increases at the associations in the early 1980s, the farmer members of the associations, aware that peso devaluations were increasing the availability of unauthorized Mexican workers, used labor contractors who hired newly arrived Mexicans to get their crops picked. Many of the contractors remained in business after the strikes ended and won enough business from growers leaving associations so that the associations went into a death spiral, unable to cover their fixed costs with ever smaller workloads. The CGA went out of business in 1986 and most of the other associations also disappeared (Lloyd *et al.*, 1988).

The UFW tried to fill the void left by the demise of the FPS and employer associations with union-run hiring halls, but they proved inefficient. Under UFW contracts, farm employers were supposed to call the UFW when they needed seasonal workers. The UFW ranked workers by their seniority with the union rather than their seniority on their farms requesting workers, making farmers unhappy, and the UFW sometimes split up families that wanted to work together, frustrating workers. The UFW abandoned hiring halls in the 1980s.

Job–worker matching in agriculture today is generally decentralized and often involves contractors. Contractors and other intermediaries match most seasonal workers and jobs in a system that can lead to simultaneous labor shortages and surpluses because of conflicting incentives. Farmers, who do not pay workers while they wait for work to begin, have an incentive to request 'too many workers too soon,' while contractors seeking jobs for their crews have an incentive to promise 'more workers sooner' to win jobs on farms. There is far more publicity of subsequent farmer complaints of labor shortages than of worker complaints of unemployment.

Farm labor contractors (FLCs) charge a fee to match farm workers with jobs. Intermediaries such as FLCs are common in labor markets where workers are hired in crews for short-duration jobs and employers may not speak the language of the workers they hire. Contractors were once a bilingual member of the crew, as with the Chinese crews in the 1870s that included a bilingual 'head boy' who arranged seasonal farm jobs for his 20–30 compatriots and worked alongside them (Martin, 2003, Chapter 2). During the 1920s, contracting became an independent business, with contractors profiting from the difference between what the farmer paid to have a job done and what the contractor paid the workers. Some of the first farm labor strikes in California involved workers protesting against farmers who hired seasonal workers only via contractors (Fisher, 1953).

The federal government began to regulate contractors in the 1960s by requiring them to register and identify themselves. Contractors today are registered by federal (www.dol.gov/whd/forms/fts_wh530.htm) and state agencies (www.dir.ca.gov/databases/dlselr/farmlic.html) that require background checks, tests of labor and pesticide laws, and bonds from which workers can collect unpaid wages. The intent of ever-stricter regulation of contractors has been to drive out of business the 'bad apples,' but enforcement data suggest that labor law violations remain common. Inspections usually find that the majority of contractors are violating at least some labor, immigration, and/or tax law; a sampling of charges is at Rural Migration News (2012).

Most contractors evade effective enforcement of labor laws for a simple reason: enforcement depends on complaints, and the employees of contractors rarely complain. The US Industrial Commission explained early in the twentieth century that contractors can 'drive the hardest kinds of bargain' with the immigrant workers they employ because they "know the circumstances from which workers come." (quoted in Fisher, 1952, p. 43). It is hard to get immigrant farm workers, who may be from the same village as the contractor and dependent on the contractor for a job as well as housing and rides to

work, to complain of violations of labor and other laws of which workers may be unaware. When there is enforcement against contractors, it is often hard to prove violations, because written contracts are rare and it is costly to obtain evidence from often illiterate and non-English speaking workers.

Throughout the US, most farm workers are hired directly by farmers, usually by bilingual foremen or supervisors who become the 'boss' in the eyes of workers. Some farm operators learn Spanish so that they can interact directly with their employees, but most rely on bilingual supervisors or turn to labor contractors to obtain seasonal workers.

Remuneration and Wages

Work is the exchange of effort for reward, and the second function of labor markets is to remunerate or motivate workers. There are two major remuneration or wage systems in agriculture: hourly and piece rate. Salaries are sometimes paid to supervisors and to some workers employed in year-round jobs in dairies.

DOL's National Agricultural Worker Survey (NAWS) in recent years found that 75% of farm jobs paid hourly wages and 25% paid piece-rate wages or a combination of hourly and piece-rate wages. Piece rates were most common in fruit-harvesting jobs, whereas nursery workers were usually paid hourly wages.

A far higher share of farm jobs paid piece-rate or incentive wages in the past, because piece rates make the cost of getting work done predictable without screening workers. For example, it costs an employer US$100 to have 1000 pounds of table grapes picked if the piece rate is 10 cents a pound regardless of whether one fast picker or three slow pickers do the work. However, worker earnings are different if one worker rather than three workers performs the work.

Before minimum wage laws applied to the farm labor market, farm employers could hire everyone who showed up to work and paid them for the work they accomplished, so that children typically earned the least and young men the most. Today, labor laws require all workers to receive at least the minimum wage. If employers pay piece-rate wages, they must record the units of work accomplished and hours worked of each worker. If a piece-rate worker does not earn at least the minimum wage, the employer must 'make up' his or her pay so the worker gets at least the minimum wage, although most employers terminate workers who do not earn at least the minimum wage.

With the minimum wage higher than the federal US $7.25 h^{-1} level in most major farm labor states, including US $8 h^{-1} in California and US$9.19 h^{-1} in Washington in 2013, many farm employers have switched to hourly wages to reduce record keeping. There are two other reasons for the rising share of farm jobs that pay hourly wages. First, farm workers have become more homogeneous, so their productivity does not vary as much as in the past when the farm workforce included children, women, and older workers rather than today's mostly young Mexican-born men. Second, new technologies allow farm employers to control the pace of work in the fields, as when a crop such as broccoli is picked and packed by workers who walk behind a machine whose speed is controlled by the driver, who can be told by the employer how fast to drive. If employers can control the pace of work, there is no need to pay piece-rate wages to induce faster work.

Piece-rate wage systems are most common when it is hard for employers to monitor the pace of work. For example, many growers of apples and oranges pay piece-rate wages of US$15–20 per 1000 pound bin to workers who climb trees and are thus often out of sight. A worker's earnings are the higher of the minimum hourly wage or his or her piece-rate earnings, and employers usually set piece rates so that the average worker earns more than the minimum wage so that the workers have an incentive to work fast even if their work cannot easily be monitored.

Piece-rate wage systems create a so-called iron triangle between the government-set minimum hourly wage, the employer-set piece rate per unit of work, and the productivity standard, the units of work per hour or day expected of a worker. In a series of suits that spanned two decades, worker advocates challenged Florida sugarcane mills that told workers that they would be satisfactory workers if they cut at least a ton of cane an hour, but, in fact, required cane cutters to cut 1.5 tons of cane an hour (Martin, 2009, Chapter 4). The minimum wage was US$5.30 h^{-1}, and the sugar mills assigned workers to cut rows of cane and 'checked out' or terminated those who were too slow. Some of the cane cutters who were checked out cut more than a ton of cane an hour, but not the 1.5 tons an hour expected by the mills, prompting the suits that alleged that workers were owed additional wages because they should have been paid US$5.30 a ton rather than the US$3.75 a ton, which they were paid (Brenner, 2001). Some of the mills settled, but the mills that contested the suits won, in part because of the difficulty of defining a piece rate in cane cutting.

Most farm employers pay farm workers the minimum wage, although some pay US$0.50 or US$1 h^{-1} more in order to attract the best workers. Most farm labor data sources report average hourly earnings, which reflect what workers actually earn under a variety of wage systems – hourly, piece rate, and hybrid. The ratio of average farm to average nonfarm average hourly earnings has been 50–60% over the past two decades, that is, farm workers earn approximately half as much as nonfarm workers. However, farm workers typically receive fewer employer-paid benefits than received by nonfarm workers, making their total compensation less than half of the average of nonfarm workers.

The cost of employing workers includes hourly wages plus mandatory and voluntary fringe benefits. Mandatory benefits are those that the employer must provide to workers, including social security, unemployment and disability insurance, and workers' compensation for work-related injuries. Voluntary fringe benefits include health insurance, paid vacations and holidays, and extra pension benefits. Hired farm workers are less likely to receive voluntary fringe benefits, or to receive lower levels of such benefits, than nonfarm workers.

The Bureau of Labor Statistics reported that the average cost of employing private sector workers in March 2012 was US $29 h^{-1}, including 70% for wages and salaries of US$20.30 and 30% for fringe benefits that cost employers US$8.70 h^{-1} (www.bls.gov/news.release/ecec.nr0.htm). Legally required benefits cost employers an average US$2.35 h^{-1} or 8% of employee compensation, whereas voluntary benefits cost employers an average 22% of employee compensation. The most

expensive voluntary benefit was life, health, and disability insurance, which cost US$2.35 or 8% of employee compensation, whereas paid vacation, holidays, and other leaves cost US$2 h^{-1} or 7%. Employer contributions for retirement benefits and employee savings cost US$1 or 4% and supplemental pay for overtime, shift differentials, and bonuses averaged US$0.85 or 3%.

Fringe benefits can be expensive to provide to farm workers because of their low earnings. Benefits such as health insurance for workers and their families that cover off-the-job injuries and illnesses require monthly payments that are independent of earnings. Under some UFW contracts, farm employers contributed US$2.70 h^{-1} for health insurance in 2012 for workers earning US$10 h^{-1}, making the employer's cost of health insurance 27% of hourly wages and far more than the average for private sector workers. Most nonunion farm employers restrict fringe benefits to year-round workers, and some report that many of their employees who are offered fringe benefits that require employee copays do not participate.

Instead of health, pension, and other benefits, farmers sometimes provide housing to attract and retain good workers. However, exposes of poor housing conditions led to higher federal and state standards for farm worker housing. As farmers are not required to provide housing, many responded to tougher housing standards by closing their housing, which pushed farm workers into cities and towns in agricultural areas where they competed with other tenants for housing.

The cost of living in cities in agricultural areas is usually more than what farmers charged for on-farm housing. Workers living in cities often pay US$50–100 a week for housing and must usually pay for rides to work, which can be US$25–40 a week. Federal and state governments make grants and loans to provide subsidized housing for farm workers, but government housing usually favors families with children, requires proof of legal status, and has long waiting lists.

As most farm workers do not live on the farms where they are employed, there are special issues associated with transportation between farm worker's homes and jobs in areas without public transportation. Most farm workers drive themselves to the field or orchard to which they are asked to report, and many carpool because they lack a vehicle or want to save fuel costs. Workers who transport nonfamily members often accept 'gas money,' raising questions about when a car pool driver becomes a commercial transport operator. Some farm operators, especially in border areas where workers walk across the Mexico–US border daily, as near Yuma, Arizona and Calexico, California, have buses to take workers to fields.

Persons who use vans to transport farm workers to fields for a fee are known as 'raiteros,' and there have been tragedies involving raitero vans. Processing tomato harvest normally runs 24 h a day during the 8-week harvest, and 13 tomato sorters who had worked all night were killed in Fresno County on 9 August 1999 when the van in which they were riding collided with a tractor-trailer truck that was making a U-turn during the early morning hours on a remote farming road. The farm-labor contractor operating the van was fined US$21 500 for allowing them to be transported in an illegally operated vehicle (Rural Migration News, 2000).

Many farm labor vans, including the one involved in the Fresno accident, have their regular seats removed and wooden benches installed along the sides of the van in order to accommodate more workers. The California Legislature responded to the tomato workers' accident with a law in 2000 that requires all vans that charge farm workers fees to have regular seats with seat belts.

Retention, Training, and Productivity

The third key labor market function is retention, which involves identifying and developing incentives to keep the best year-round workers employed on the farm and encouraging the best seasonal workers to return to the farm the following year. Most US employers have formal systems that involve supervisors to evaluate workers periodically, and these evaluations are used to determine promotions and wage increases.

Few farm employers have formal personnel systems. Instead, the two major methods of recruitment and worker evaluation illustrate agricultural extremes in personnel practices. Some farmers, especially those who work closely with one or a few year-round workers in dairies and similar operations, ask current employees to refer friends and relatives to fill vacant jobs. Current workers tend to refer only friends and relatives who can perform the work, and they usually orient and train the workers they recommend. In this way, network recruitment simplifies the task of finding and training workers (Martin and Perloff, 1997).

The other personnel extreme involves growers who hire crews of seasonal workers via contractors or foremen. These operators often rely on intermediaries such as contractors to bring crews of interchangeable workers to the farm to perform a particular task such as weeding or harvesting. Contractors and foremen also rely on network hiring, having some of their 'regular' workers recruit friends and relatives, but the farmer rarely knows who is in the crew or the exact worker turnover rate.

Crew-based hiring explains why recruitment and retention are often part of the same labor market function. An analogy to obtaining irrigation water may be helpful to understand agricultural recruitment and retention options. One way to irrigate crops is to flood fields with water so that some trickles to each tree or vine; the other extreme involves laying plastic pipes on or under the ground and dripping water and nutrients to each tree or vine. If water is cheap, farmers flood fields with water; if water is expensive, farmers may invest in drip irrigation systems.

The analogy to farm worker recruitment and retention is clear. Do farmers collectively flood the labor market with workers, usually by getting border gates opened or left ajar, so that there are enough workers to fill all seasonal jobs, or do they recruit and retain the best farm workers for their operation? The best way to ensure that there is plenty of irrigation water is to invest in more dams and canals; the best way to flood the labor market is to invest in politicians willing to provide easy access to foreign workers.

Guest Workers: Braceros and H-2A Workers

Foreign-born workers have long been a large share of the hired farm workforce in the western states. Most stayed in seasonal

farm work a generation or less, until they could find nonfarm jobs that offered higher wages and year-round employment. The children of seasonal farm workers educated in the US rarely followed their parents into the fields, so farmers constantly worried about who would replace the farm workers who left for nonfarm jobs.

During the late nineteenth century, most seasonal farm workers on large farms in the western states were Chinese and Japanese, but the source of new farm workers changed in the twentieth century to Mexico. Mexicans were admitted as guest workers under two Bracero (strong arm) programs, one between 1917 and 1921 and the other between 1942 and 1964 (Martin, 2003, Chapter 2). Today, Mexican guest workers are admitted under the H-2A program, a guest worker program that many farm employers consider too bureaucratic and expensive. With half or more of farm workers unauthorized (NAWS), farmers want Congress to modify the H-2A guest worker program or create a new guest worker program for agriculture.

Mexican Braceros

The first Mexico–US Bracero program began on 23 May 1917, as farm employers complained of labor shortages during World War I. The US DOL, which included the Bureau of Immigration at the time, allowed the admission of Mexicans primarily for 'employment in the sugar beet fields of California, Colorado, Utah, and Idaho and the cotton fields of Texas, Arizona, and California' (Scruggs, 1960, p. 322). By the early 1920s, Mexicans were 'the principle workforce in many southwestern farming areas' (Scruggs, 1960, p. 319).

The American-workers-first principle of subsequent guest worker programs was laid out in this first Bracero program. US farm employers had to recruit US workers and to make written offers of 'wages, housing conditions, and duration of employment.' If they could not find US workers, they could hire Mexican Braceros, who were to receive the 'prevailing wage,' which was the wage paid "for similar labor in the community in which the admitted aliens are to be employed." (CRS, 1980, p. 10). Farm employers had to provide housing for Braceros, and this housing had to satisfy state laws or standards set by DOL if there were no state laws governing farm worker housing.

There were several features of the first and subsequent guest worker programs that proved troublesome. For example, some of the wages earned by Braceros were withheld by the US farm employers, deposited with the US Postal Savings Bank, and then transferred to Mexico, where Braceros who returned were supposed to receive these forced savings. However, many returned Braceros never received these withheld wages. A second issue involved the debt accumulated by Braceros in the farm labor camps where they lived. Some Braceros wound up owing more than the wages they earned to the US farm where they worked because of purchases of food and alcohol in the camps. The Mexican government complained about these issues, and the two governments allowed the Bracero program to end in 1921. Some ex-Braceros migrated illegally to the US during the 1920s because there was no US Border Patrol until 1924.

During the 1930s, Dust Bowl migration brought 1.3 million people known as Okies and Arkies to California, swelling the state's population by 25%. Some sought to be farm workers, and they soon learned that California's commercial farms hired crews of seasonal workers when needed, not year-round hired hands who lived and ate with the farmer's family. Some Dust Bowl migrants wound up in tent camps known as Hoovervilles, where unions and 'agitators' highlighted the inequities of large landowners who benefited from government irrigation projects and farm programs but paid seasonal workers low wages only when they were needed. Dust Bowl migrants were US citizens who could vote, and there was concern that Hoovervilles could become a fertile breeding ground for Communists and others who wanted to make major changes in the US socioeconomic system.

Two congressional committees examined farm labor conditions in California and other western states during the late 1930s. They agreed that there were serious problems but disagreed on the appropriate federal response (Martin, 2003, Chapter 2). The House Committee on Un-American Activities warned that dissatisfaction in the Hoovervilles opened the door for Communists and urged vigilance and enforcement against 'Communist agitators.' Many cities and counties in agricultural areas responded with ordinances, later declared unconstitutional, that prohibited 'labor agitation,' rallies, and picketing.

The Senate Education and Labor Committee, however, concluded that the solution to farm labor discontent was to extend collective bargaining rights to farm workers. The National Labor Relations Act of 1935 gave private sector nonfarm workers the right to form unions and to bargain collectively with their employers, in part to reverse the wage cuts that were thought to be prolonging the Depression. However, farm workers were excluded from the NLRA under the theory that most were hired hands with the same interests as farmers, that is, farm workers wanted government programs to raise farm prices, not legal protection to form unions.

Congressional disagreements about how to respond to farm worker's discontent and the outbreak of World War II shifted government's attention elsewhere. The tenor of the farm labor debate changed, from what to do about surpluses of farm workers during the 1930s, to complaints of labor shortages in the early 1940s. California farmers requested Mexican Braceros in 1941, but their request was rejected by the DOL at the behest of the California governor (Rasmussen, 1951, p. 200). However, a federal interagency committee concluded that Mexican workers would be needed to harvest US crops in the fall of 1942, and Mexico and the US signed a new Bracero agreement on 23 July 1942.

The Bracero program was small during World War II, admitting a peak of 62 000 Mexican workers in 1944. However, the program expanded in the 1950s, admitting a peak of almost 450 000 Braceros in 1956. The availability of Bracero guest workers held down farm wages, enabling labor-intensive agriculture to expand in California and other western states at a time when the interstate highway system was reducing the cost of transporting fresh fruits and vegetables for long distances. Rural Mexicans gained familiarity with US farm jobs, and some migrated illegally to the US after the Bracero program ended in 1964. Many Mexican-Americans, who had to compete with Braceros in the fields, moved from the agricultural areas of California to cities such as Los Angeles and San Jose, where there were no Braceros.

Numerous commissions and reports criticized farmers for mistreating and underpaying Braceros and US farm workers, but the CBS documentary, Harvest of Shame, that aired on Thanksgiving Day in November 1960 prompted action. Newly elected President, John Kennedy, ordered the US DOL to enforce minimum wage and other regulations that aimed to protect US and Bracero workers, which raised labor costs and prompted labor-saving mechanization in some field crops including cotton harvesting and sugar beet thinning. The Kennedy Administration announced that the Bracero program would end in 1961, but in response to farm employer pressure, the program continued until 31 December 1964.

H-2A Workers

After the Bracero program ended, many California farmers expected to employ Mexican workers under the H-2 guest worker program, which was established in the 1952 Immigration and Nationality Act and was used to import Caribbean workers who primarily hand cut sugarcane in Florida and harvested apples along the eastern seaboard. Unlike the Bracero program based on a Mexican–US Memorandum of Understanding, the H-2 program was part of the US immigration law.

However, the H-2 program included requirements that drew protests from California farmers, such as a requirement to pay H-2 guest workers the highest of three wages: the federal or state minimum wage, the prevailing wage for similar work in the area, or the DOL-calculated Adverse Effect Wage Rate (AEWR), which was typically the highest of the three. The DOL also limited H-2 guest workers to 120 days in the US, which was not a problem in the eastern states that had shorter growing seasons, but California farmers wanted to employ Mexican workers for 11 months a year.

The DOL Secretary, Wirtz, asserted that the purpose of these H-2 regulations was to reduce admissions of foreign workers in order to reduce unemployment among US farm workers. Farmers were unhappy, and Senators from California and Florida in 1965 introduced legislation to transfer responsibility for certifying farm employer's requests for foreign workers from the DOL to the USDA. Their effort failed on a 46:45 vote because Vice President Hubert Humphrey cast a vote to break the previous tie and keep the administration of the H-2 program within the DOL (Congressional Research Service, 1980, p. 42).

Most H-2 guest workers between the mid-1960s and -1980s were Jamaicans who cut sugarcane in Florida and picked apples from Maine to Virginia. There were ongoing disputes between worker advocates who believed that the DOL was failing to protect US workers and farm employers who believed that the DOL was putting unnecessary hurdles between them and the H-2 guest workers on whom they relied. For example, apple growers sued the DOL when it ordered them to hire inexperienced Louisiana workers who responded to their required recruitment advertisements rather than experienced Jamaican apple pickers. However federal courts ruled that US employers must hire US workers who can do the job even if the foreign workers are more productive.

The H-2 program was changed into the H-2A program by the Immigration Reform and Control Act of 1986, which changed the DOL regulations and incorporated them into law, making them harder to change. Under current regulations, US farmers anticipating shortages of workers to fill temporary or seasonal jobs can request certification from the DOL to employ H-2A guest workers. The DOL certifies farm employer's requests for H-2A guest workers and if it finds that US workers who are 'abled, willing, and qualified' are not and will not be available to fill the job vacancy for which the employer is requesting guest workers and that the employment of the H-2A workers will not adversely affect similar workers, the DOL certifies the farm employer's need for guest workers.

Approximately 7000 farm employers request certification to fill more than 90 000 farm jobs a year with H-2A workers, and the DOL approves more than 90% of their requests. To be certified by the DOL to hire H-2A guest workers, farm employers must offer the highest of the minimum, prevailing, or AEWR wage and free and approved housing, meals, or cooking facilities. They must promise to reimburse workers for their inbound travel costs after 50% of the employer-specified contract is completed and provide work or pay wages for at least three-fourth of the contract period. The employer must submit job offers that include these promises to local Employment Service offices and interview any US workers who respond to their recruitment. Employers attach the DOL's certification to a request to the DHS, which transmits its approval to a US Department of State consulate abroad where foreign workers are given H-2A visas. Most farm employers use an agent or belong to an association that handles the paperwork and visa issuance.

Approximately 10% of H-2A certifications each year are in North Carolina, where the North Carolina Growers Association charges its member growers who primarily produce vegetables and tobacco US$1000 for each H-2A worker. The next leading H-2A states are Georgia and Virginia, where, as in North Carolina, ex-DOL or state officials who used to administer the H-2A program established agencies to help farm employers navigate the certification process. The H-2A program is expanding fastest in Washington, where some apple growers who were required to terminate unauthorized workers, after government audits of their employment records, built the housing required by the H-2A program and were certified to employ H-2A workers (Rural Migration News, 2010).

Proposed Reforms

Farm employers would like three major changes to the H-2A program that could change the farm labor market by increasing the share of guest workers among US crop workers. First, farm employers would like to 'attest' or promise in documents filed with the DOL that they need guest workers and are paying prevailing wages, ending the current processes that involves the DOL supervising their efforts to recruit US workers. Attestation would effectively shift control of the border gate from the US DOL to employers.

Second, rather than provide free housing to H-2A workers, farm employers would like to pay a housing allowance of US $\$1–2\ h^{-1}$, depending on local costs to rent two-bedroom units that are assumed to house four workers, if state governors certified that there was sufficient rental housing for the guest

workers in the area where they would be employed. Substituting a housing allowance for providing housing would make it much easier for farm employers in California and other states where most labor-intensive agriculture is in urban or metro counties with strict zoning regulations to hire guest workers.

Third, farmers would like the AEWR, the special minimum wage that must be paid to guest workers, to be rolled back and studied. The AEWR for California in 2012 was US$10.24 h^{-1}, whereas the state's minimum wage was US$8, so reducing the AEWR to US$9 h^{-1} or less would help to offset the cost of the housing allowance.

These three employer-favored reforms to the H-2A program are included in the Agricultural Jobs, Opportunity, Benefits, and Security Act (AgJOBS), a proposal negotiated between farm worker and farm employer advocates in the fall of 2000 (Martin, 2005). Many farm worker union and farm employer groups support AgJOBS, but not the American Farm Bureau Federation, which in the fall of 2012 unveiled its own proposed new guest worker program that was embraced by many other farm groups that joined the Agriculture Workforce Coalition (www.agworkforcecoalition.org).

Under the AFBF proposal, farm employers would have two options to employ guest workers. The first would give an unlimited number 11-month visa to foreign workers who could move between different US farm employers who were registered with the USDA. These free-agent guest workers would have to leave the US for a month a year but could return year after year. The second option would allow farm employers to offer renewable 12-month visas to foreign workers who would be tied to their farms. These contract workers would have to leave the US at least 30 days every 3 years.

Unions

Unions are organizations of workers whose purpose is to raise wages and improve conditions for members who pay the dues that support the union. Unions put pressure on employers in four major ways – with strikes that reduce the supply of a good or commodity; activities that reduce the supply of labor or preserve jobs, such as limits on immigration or clauses in collective bargaining agreements that limit mechanization; political activities to obtain favorable laws and their interpretation; and consumer boycotts to reduce the demand for particular commodities. Employers counter these union weapons by replacing workers who strike, engage in political activities to win laws favorable to management rights, and by advocating more immigration and other policies that increase the supply of labor.

US union membership has been in a long-term decline, so that only 11% of the 128 million wage and salary workers were union members in 2012, down sharply from 20% in 1983 (www.bls.gov/news.release/union2.nr0.htm). There were 14.3 million union members in 2012, including seven million private sector workers and 7.3 million public employees. Local government workers had the highest unionization rate, 42%, whereas agriculture had the lowest, 1.4%. By occupation, education workers had the highest unionization rate, 35.4%, and farming had the lowest rate, 3.4%.

Farm workers are an attractive target for unions because there are millions of farm workers, their wages are relatively low, and farm workers have been receptive to promises of higher wages and better working conditions. But organized farmers had the upper hand over unorganized farm workers throughout most of the twentieth century, largely because most farm workers found it easier to exit the farm labor market for upward mobility rather than join or form a farm labor union to voice collective demands for higher wages and benefits. As a result, there have been few persisting union–management agreements in agriculture. The longest collective bargaining relationship in California agriculture is between the Teamsters and Bud Antle (now Dole Food Company), which began in 1961. US unions such as the United Auto Workers and the United Steel Workers, by contrast, have had continuous relationships with major auto and steel makers since the mid-1930s.

The scarcity of union–management agreements in agriculture, and the fact that few have persisted, reflects several factors including the tendency of the most able farm worker union leaders to move on to nonfarm jobs and the fact that many farm worker organizers in the past were radicals seeking to transform the economy. During the twentieth century, farm employers often unified rural residents and local law enforcement agencies against 'outside agitators,' and federal and state governments were slow to extend labor relations rights to farm workers, making it hard to develop sustainable farm worker unions.

Pre-UFW Unions

The American Federation of Labor (AFL) began as a national organization of craft unions in 1886. The AFL's member unions, such as carpenters or bricklayers, organized workers into unions that reflected worker crafts or occupations. In 1903, several AFL unions announced plans to organize farm workers, but their union drive soon sputtered, in part because the AFL unions feared that organizing farm workers would upset farmers, who could use their power in Congress and state legislatures to restrict all union activities.

The Industrial Workers of the World (IWW) or 'Wobblies' was a revolutionary union founded in 1905 by Eugene Debs and other radical labor leaders who felt betrayed by the AFL unions. Their goal was to replace what the IWW called a 'wage slave system' of employers and employees with worker-run cooperatives. The IWW wanted to organize all workers into 'one big union' that included skilled as well as unskilled workers and minorities such as Chinese and Japanese farm workers, who were excluded from most AFL unions.

The IWW successfully organized many of the wheat harvesters in the Midwestern states early in the twentieth century. A peak of 250 000 mostly white workers migrated from Texas to Canada, harvesting wheat and other grains from south to north. Most traveled by riding freight trains without paying, and migrants without an IWW 'red card' were sometimes prevented from riding the rails. A typical IWW 'plan of action' at a particular farm involved an IWW organizer or 'job delegate' getting a job and helping the workers to organize a strike.

Some employers tried to harvest crops with strikebreakers, which often led to violence and the arrest of 'outside agitators.'

In California, IWW organizers targeted migrants who harvested wheat, the so-called 'harvest or bindle stiffs' (Steven Street, 1998). IWW organizers mingled with farm workers during the winter months when they 'holed up' in cities, explaining from soapboxes why workers needed to support radical change in the US economic system to improve their wages and living conditions. Local authorities often used unconstitutional means to restrict the activities of IWW organizers, which gave its message more publicity. For example, Fresno in 1910 denied IWW organizers the right to make speeches and distribute literature, but publicity about this unconstitutional interference with free speech helped to raise awareness of and membership in the IWW. The IWW claimed 10 000–12 000 members in northern California in 1912 (Jamieson, 1945, p. 60).

The Wheatland hops riots of 1913 illustrate the clash of extremes in farm fields that led to violence and ultimately the demise of the IWW (Jamieson, 1945, 60–63; Daniel, 1981, 89–91). Wheatland is a small community 30 miles northeast of Sacramento in Yuba County, and harvesting the hops used to make beer was labor intensive. Many harvesters were white men who responded to handbills distributed by farmers such as Durst, who advertised for 2700 workers to harvest hops in August 1913 and at a higher-than-usual piece-rate wage of US$1 per 100 pounds.

When 2800 workers traveled to Wheatland, Durst cut the piece rate to US$0.90, because he had housing only for 1700 workers. The workers protested, and IWW organizers helped them to form a protest committee and demand that Durst pay the US$1 advertised wage. Durst called the local sheriff on 3 August 1913, saying that the IWW was trying to take over his ranch. When the sheriff tried to arrest strike leaders, a district attorney, deputy sheriff, and two workers were killed. Most of the workers on the Durst ranch left before the National Guard arrived to restore order, and no contract was signed between Durst and the IWW.

IWW leaders were convicted of inciting a riot and were sentenced to prison. Governor Hiram Johnson appointed a Commission on Immigration and Housing in 1913 to examine what became known as 'the first California labor cause célèbre.' Economist Carleton Parker concluded that the Wheatland riot "embodied the state's great migratory labor problem," the broken wage promises of employers (Daniel, 1981, p. 91). Parker and the Commission urged growers, despite the 'general superabundance' of farm workers, to honor the wage promises they made in handbills and urged the state to enact and enforce housing and sanitation standards in farm labor camps.

The peak year for farm worker strikes was 1933, and the reason was that the prices received by farmers rose but farm worker wages did not. Farmers' prices fell between 1929 and 1932, the US unemployment rate reached 24%, and the farm workforce swelled with urban workers who lost their jobs returning to the fields. California farmers cut wages from 35–50 cents an hour in 1929–30 to 15–6 cents in 1933. The Communist-dominated Cannery and Agricultural Workers Industrial Union (CAWIU) followed the IWW pattern of taking over the leadership of spontaneous worker protests and strikes and helping workers to present demands to employers. CAWIU-led strikes were often violent, in part because growers and their foremen were often deputized to help local law enforcement.

There were 37 strikes involving 48 000 farm workers in 14 crops in California in 1933, culminating in an October cotton harvesters strike. Harvest-time strikes during the spring and summer usually resulted in wage increases, so that by fall, workers were prepared to strike again to get a wage increase for picking cotton, the crop that employed most of the workers. Cotton farmers met in September to set a piece-rate wage of pay 60 cents per 100 pounds of cotton picked, up from 40 cents in 1932 but less than the US$1.50 of 1929. Cotton harvesters were expecting wages to rise to at least US$1, and the CAWIU called a strike on 4 October 1933 to support its demand for a US$1 per 100 pound piece rate. Growers evicted 10 000–20 000 strikers and their families from on-farm labor camps, and most moved into CAWIU-run tent camps.

The strike was condemned by farmers but were supported by local leaders. A Tulare newspaper editorialized that "the strike would vanish into thin air overnight if the outside agitators were rounded up and escorted out of the county, as they should be" (Jamieson, 1945, p. 103). Farmers tried to break up striker rallies, and two workers were killed in Pixley, CA, USA. State officials urged local authorities to disarm the growers, who instead issued more gun permits, prompting the reporters who arrived to cover the strike to turn against growers for refusing mediation.

The strike threatened the cotton crop. The Governor appointed a UC fact finding missions that recommended a 75-cent piece rate. Banks persuaded farmers to pay 75 cents by threatening to withhold financing for the 1934 cotton crop, and the Governor announced that workers who did not go to work by 16 October 1933 would be denied state relief in the winter months. The 75-cent wage appeared to be at least a partial victory for the CAWIU, and it prompted farmers to form a new organization, the Associated Farmers of California, which persuaded most rural counties to enact antipicketing ordinances that were used to prosecute CAWIU organizers.

The Associated Farmers, financed largely by nonfarm banks, railroads, canneries, public utilities, and the Industrial Association of San Francisco, provided funds to local law enforcement to monitor CAWIU leaders. It succeeded, and 14 CAWIU leaders were convicted of instigating violence and were sent to prison in July 1934. The CAWIU showed that farm workers could be organized to strike in support of higher wages, but the CAWIU's policy of not signing contracts, and its communist orientation, persuaded growers to organize themselves into effective antiunion associations.

United Farm Workers

Cesar Estrada Chavez (1927–93) is the best-known US Mexican-American: more US schools, streets, and libraries are named after Chavez than any other Hispanic. Chavez was born in Arizona, and his family lost its farm and became migrant farm workers in the 1930s.

Chavez left a job registering voters in the Sal Si Puedes (Get out if you can) barrio of San Jose, California, in 1962 to help

farm workers in the Tulare county city of Delano. With the help of school teacher Dolores Huerta, Chavez launched the Farm Workers Association (FWA) to help farm workers with government paperwork in exchange for US$3.50 monthly dues. In 1964, the FWA was renamed the National FWA (NFWA), and in 1965 the NFWA conducted a successful rent strike against the public housing authority in Tulare County.

In the spring of 1965, when Coachella Valley table grape growers offered workers US$1.25 h^{-1}, the Filipino-dominated Agricultural Workers Organizing Committee called a strike against to demand the same US$1.40 h^{-1} that had been paid to Mexican Braceros in 1964. Growers raised to US$1.40 did not recognize the AWOC as the representative of table grape pickers. When the harvest moved north to Delano, growers again announced a US$1.25 h^{-1} wage, prompting the AWOC to strike on 8 September 1965 for US$1.40 h^{-1}. Chavez's NFWA joined the AWOC, and growers harvested their grapes with FLC-supplied workers and did not recognize the AWOC–NFWA as a union for their workers. The AWOC–NFWA merged into the UFW union in 1967 (www.ufw.org).

Chavez quickly assumed leadership of the strike and urged a consumer boycott and nonviolent resistance to turn the struggle over wages into a case of powerless farm workers against powerful agribusiness. His major innovation was to apply pressure to growers when there were no crops to be harvested, and to enlist unions, churches, students, and politicians to picket liquor stores before Christmas 1965, urging Americans not to buy the liquor products of Schenley, a conglomerate with 3350 acres of vineyards near Delano.

The Schenley boycott was successful: liquor sales fell, and Chavez kept the boycott in the news with a succession of high-profile visitors to Delano. For example, the US Senate Subcommittee on Migratory Labor held a hearing in Delano in March 1996 that featured a televised argument between Senator Robert Kennedy (D-MA) and the Kern County sheriff over constitutional rights. The sheriff said that he arrested UFW supporters because he knew they were about to break the law, prompting Kennedy to counter that Chavez and the farm workers had the right not be arrested until they broke laws. The NFWA began to march from Delano to Sacramento on 17 March 1966, and as the marchers neared Sacramento for an Easter Sunday rally, Schenley agreed to raise wages by 40%, from US$1.25 to US$1.75 an hour, approximately twice the minimum wage.

The UFW collected signatures from farm workers that authorized the UFW to represent them at other farms. It then sent letters to farmers asserting that the UFW represented their workers and asked the farmer to sign the union's standard contract or begin negotiations. If the farmer refused, the UFW threatened a consumer boycott, and its boycott threats led to contracts with wineries including Almaden, Christian Brothers, and Paul Masson.

The UFW in January 1968 sent we-represent-your-workers letters to the state's table grape growers. The growers did not respond, and the UFW launched a nationwide boycott of grapes, La Causa, that made Cesar Chavez a household name. The grape boycott is considered one of the most successful consumer boycotts in the US history. According to a September 1975 Harris poll, 12% of Americans avoided grapes in the late 1960s and early 1970s, and per capita grape consumption fell from 3.4 pounds per person in 1968 to 2.2 pounds per person in 1970–71. Chavez, hailed as the Latino Martin Luther King, was featured on the cover of Time magazine on 4 July 1969 under the headline, The Grapes of Wrath.

Grape grower Lionel Steinberg signed a contract with the UFW on 10 April 1970, ending La Causa. Other grape growers followed, signing contracts that offered harvesters US $1.75 h^{-1}, and the UFW soon had 150 contracts covering 20 000 workers. The contracts included clauses restricting mechanization and pesticide usage, and the UFW announced plans to follow in the footsteps of construction and longshoremen unions by being the organizing institution in what had been a casual labor market, with UFW hiring halls allocating work according to each worker's seniority with the UFW.

The UFW had a rival, the Teamsters union that represented truck drivers as well as many of the workers employed in canneries and processing sheds. When the UFW sent its 'we-represent-your-workers' letters to lettuce growers in 1970, most responded that their field workers were already represented by the Teamsters. The UFW attacked the Teamsters and the growers, emphasizing that many workers did not know the Teamsters represented them and that 'secret contracts' were signed to avoid the UFW.

The UFW was an early supporter of the Democratic candidate for governor in 1974, Jerry Brown. After he won the November 1974 election, Brown made the enactment of a farm labor relations law his top priority. The Agricultural Labor Relations Act (ALRA) was signed into law on 5 June 1975 so that the first elections could be held during the peak harvest period, and 15 artichoke workers employed by Molera Agricultural Group near Castroville made history by casting votes in the first Agricultural Labor Relations Board (ALRB)-supervised election in September 1975. The UFW and the Teamsters competed vigorously in these first ALRA elections. There were elections on five or more farms every day in the fall of 1975, a total of 418 in the first 5 months the ALRA was in effect. The UFW won 198 or 55% of the 361 elections in which a winner was certified, and the Teamsters 115% or 32%.

Unionization was expected to transform to farm labor market, double farm wages in California and the rest of the US, and close the farm–nonfarm wage gap. However, experienced observers were more skeptical about unionization. Fuller and Mason (Fuller and Mason, 1977 p. 80) concluded that farm worker unionization will "continue to be more exceptional than dominant" (1977, p. 79), but added that farm worker unions representing a small share of farm workers could nonetheless 'become politically influential with respect to laws and programs affecting all farm workers.'

Rising farm wages and the introduction of fringe benefits for unionized farm workers raised labor costs and spurred efforts to develop labor-saving machines including some developed by the University of California researchers. The UFW and the California Rural Legal Assistance organization sued the UC in 1978, charging that researchers were using tax monies to develop machines that displaced farm workers and small farmers. Stopping mechanization research became the UFW's 'No. 1 legislative priority' (Business Week, 30 January 1978) and was largely achieved as rising unauthorized migration weakened the UFW and reduced wage increases (Martin and Olmstead, 1985).

In 1979, the UFW won a Pyrrhic victory from which it never recovered. In the Imperial Valley next to the Mexican border, the UFW had expiring contracts with 26 vegetable growers. Most were negotiated in 1975–76 and raised wages from US$3.11 h^{-1} to US$3.70 h^{-1} by 1978; the federal minimum wage rose from US$2.10 in 1975 to US$2.65 in 1978. The UFW demanded a 42% wage increase for entry-level workers, which would have raised them from US$3.70 h^{-1} to US$5.25 h^{-1} and, according to farm employers, more than doubled labor costs. Growers countered with an offer of a wage increase of 21% over 3 years, prompting the UFW to call strikes in mid-January 1979. The UFW and employers placed advertisements in Mexicali newspapers (most workers lived in Mexico and commuted daily to US farm jobs), explaining the demands and offers.

The strike involved some 4300 workers and affected some of the largest vegetable growers, including Bruce Church and Sun Harvest, a subsidiary of United Brands (Chiquita bananas). The UFW complained that growers encouraged unauthorized migration to get strike breaking workers from Mexico, battles on the picket lines resulted in the death of a UFW member. The strike and disease reduced the supply of winter lettuce by one-third. However, the demand for lettuce is relatively inelastic, meaning that the quantity sold does not vary much with its price, so lettuce prices tripled and grower revenues doubled (Carter *et al.*, 1981). Many sympathetic observers questioned the UFW's strategy. One article noted, "Although Chavez claims the union is striking to win wage parity with industrial workers, most observers say he purposely brought on the strike in an attempt to rally the union." (Business Week, 5 March 1979).

The UFW strike was losing momentum in the summer of 1979, when Meyer Tomato in the Salinas Valley agreed to raise wages by 43% over 3 years to US$5.29 h^{-1} by 1982. The wage leader, Sun-Harvest, agreed to a US$5.25 minimum wage and newspapers hailed the 'record contracts' won by the UFW. The UFW charged that the lettuce growers who did not sign contracts offering US$5.25 h^{-1} violated the ALRA by failing to bargain in good faith when they broke off negotiations, raised wages, and began to hire replacement workers. The ALRB agreed with the UFW and ordered the Imperial Valley growers to pay tens of millions of dollars of makewhole wages and benefits to farm workers including those who went on strike. This ALRB decision was eventually overturned by appeals court rulings that the growers were engaged in hard rather than unlawful bargaining, and many of the firms that signed contracts with the UFW went out of business or did not renegotiate with them.

The UFW lost contracts and influence in the 1980s and was only a shadow of its former self when Chavez died in 1993. President Clinton awarded Chavez a posthumous Medal of Freedom in 1994, and Chavez was widely hailed as the Latino Martin Luther King who used a union of farm workers to call attention to the issues of Hispanic farm workers. Chavez said he wanted to be remembered for "attack[ing] that historical source of shame and infamy that our people in this country lived with: the humiliation brought upon generations of dark-skinned farmworkers by corporate agribusiness."

Arturo Rodriguez, Chavez's son-in-law, became the new UFW president in 1994 and settled many long-running labor disputes by dropping charges that particular employers violated the ALRA in exchange for contracts. For example, the UFW settled a long-running dispute with lettuce grower Bruce Church Inc (BCI) in May 1996 by signing a 5-year collective bargaining agreement, but BCI soon stopped growing lettuce. The UFW won a mandatory mediation amendment to the ALRA in 2002 that allows either employers or unions to request mediation to negotiate a first contract. If the mediator fails to help the parties reach agreement, he can recommend a contract that the ALRB can impose on the parties (Martin and Mason, 2003).

Unions play a relatively small role in the farm labor market of California and most other major farming states. Four major explanations have been advanced for the relative paucity of unions in agriculture: union leadership failures, politics, farm employer changes, and immigration. The union leadership failure is the most common explanation, with most analyses asserting that Cesar Chavez was a charismatic leader able to articulate the hopes of farm workers, but Chavez and the UFW were unable to negotiate and administer union contracts to the satisfaction of employers and experienced farm workers. As workers left for nonfarm jobs, the UFW was unable to organize newcomer farm workers (Pawel, 2009; Ganz, 2009).

The second explanation involves the politics surrounding the ALRB, the state agency that administers the ALRA. Democratic governors made key appointments to the ALRB between 1975 and 1982, Republicans between 1983 and 1998, Democrats between 1999 and 2004, Republicans between 2005 and 2011, and Democrats since then. This 'it's-all-politics' theory holds that the effectiveness of a self-help labor relations law depends on which party makes appointments to the ALRB, the agency that enforces the law (Majika and Majika, 1982).

The third explanation emphasizes that union successes of the 1960s and 1970s were mostly with employers who hired farm workers directly and had brand names that made them vulnerable to union-led boycotts of their farm and nonfarm products. Boycott-vulnerable corporations such as Seven-Up, Shell Oil, and United Brands sold their California farming operations in the 1980s, and the UFW found it harder to deal with the independent growers who replaced them. There was also an increase in the use of intermediaries such as contractors, and the combination of independent growers and intermediaries such as FLCs reduced union power.

The fourth explanation is immigration. The UFW had its maximum impacts on farm wages between the mid-1960s and the early 1980s, when legal and unauthorized immigration was low. (Illegal) migration began rising in the 1980s, rose more in the 1990s, and peaked during 2002–07, when an estimated 500 000 unauthorized foreigners a year, including 300 000 Mexicans, settled in the US. These migrants increased the supply of farm workers and made it hard for unions to win wage and benefit increases via collective bargaining (Martin, 2009).

Farm Labor Organizing Committee (FLOC), Coalition of Immokalee Workers (CIW), and Other Unions

States with large numbers of farm workers include California, Florida, North Carolina, Texas, and Washington. There is a

significant farm worker union activity in North Carolina and Florida.

The Ohio-based FLOC, founded in 1967 by Baldemar Velasquez, became a union in 1979 and refined the UFW's boycott strategy (www.floc.com). FLOC threatened consumer boycotts of the pickle and tomato products processed and sold by food companies such as Campbell's and Heinz unless they persuaded the farmers who grew pickles and tomatoes, and hired workers to pick them, to recognize FLOC as the farm workers' bargaining representative.

In 1985, after a march from Ohio to Campbell headquarters near Philadelphia, FLOC reached three-way agreements with Campbell's Vlasic subsidiary and its tomato and pickle growers in Ohio and Michigan. Farmers who wanted to grow tomatoes and cucumbers for Vlasic recognized FLOC as the union for approximately 800 farm workers, and Vlasic raised the prices it paid to farmers to cover the higher wage and benefit costs of the contracts. Because farm workers are not covered by labor relation laws, there was no need for elections to determine worker preferences, and there were none. FLOC has offices in Florida, where many of the cucumber pickers live when they are not in Ohio, and in North Carolina, where FLOC represents pickle harvesters employed by growers who deliver cucumbers to Mount Olive.

FLOC is pressuring tobacco firms to establish labor standards for the farms from which they buy tobacco, extending its strategy of using pressure on buyer of farm commodities to improve wages and working conditions for farm workers. Reynolds American in 2012 agreed to meet with FLOC and discuss the conditions of workers on the North Carolina farms from which it buys tobacco. FLOC says that 30 000 workers are employed in North Carolina tobacco fields and it represents 27 000 farm workers in Ohio and North Carolina.

The CIW in Florida tried to persuade tomato growers to raise piece-rate wages for a decade before turning to a boycott of fast-food chains that bought mature-green tomatoes (www.ciw-online.org), those that are picked green and ripened with ethylene to turn them red. Beginning with Taco Bell in 2005, most major fast-food chains signed agreements with the CIW, agreeing to pay an additional 1.5 cents a pound for the Florida tomatoes they buy, with one cent going to pickers, doubling the usual US$0.35 for picking a 35-pound bucket of tomatoes to US$0.70.

The CIW's Fair Food Program (FPP) includes mandatory training on worker rights and a grievance procedure. Tomato growers found to be in violation of FPP standards risk lose the right to sell to fast-food chains. The Fair Food Standards Council (http://fairfoodstandards.org), which monitors and audits the FPP, reported that US$6 million in extra payments were made to tomato pickers in 2010–11 and 2011–12.

Collective bargaining aims to enable farm workers to help themselves to increase wages and working conditions. During the twentieth century, farm worker union activities have been 'much ado about nothing' because diverse farm workers often share only one goal: finding a better nonfarm job as soon as possible.

Farmers have been well-organized to resist farm worker unions, and the federal government has not extended labor relations rights to farm workers.

At the dawn of the twenty-first century, there is more agreement on trends affecting farm workers and the farm labor market than on what these trends mean for unions and collective bargaining. The major trends likely to influence the relative strength of unions and farm employers include: the rapid growth of the Hispanic population, presumed to be sympathetic to farm worker unions and thus to increase support for boycotts; continued immigration that may make it hard for unions to use traditional weapons such as strikes to push up wages; and changes in the food sector, such as the consolidation of grocery stores that tends to put downward pressure on farm prices. Farm worker unions believe that an amnesty for currently unauthorized farm workers would embolden them to join unions and press for wage increases. Farm employers prefer guest workers who may be harder to organize.

The realization by farm worker unions and farm employers that their struggles are being played out on a larger stage has broadened the interest of unions in pesticides, water, and other issues. The UFW, for example, remains a major player in Democratic Party politics in California and influences especially Latino lawmakers on issues such as allowing farmers to sell their water to cities, benefiting the farmers but reducing jobs for farm workers, using state funds to promote farm commodities, and developing tighter regulations on pesticides.

Conclusions

Agriculture is a peculiar industry with a unique labor market. The three R-functions of all labor markets are dealt with differently in agriculture. Farmers often rely on intermediaries such as contractors to assemble crews of workers and move them from farm to farm, many farm operators use piece-rate wage systems to give workers an incentive to work fast without close supervision, and farm employers have more often cooperated to ensure that they collectively have enough seasonal workers to fill farm jobs rather than individually developing mechanisms to identify and retain the best workers on their particular farm.

Approximately three-fourths of US hired farm workers were born abroad, usually in Mexico, and half of all farm workers are not authorized to work in the US. Farm employers believe that US workers shun especially seasonal farm jobs and want the government to make it easier for them to hire foreigners as legal guest workers. Twice in the past, between 1917 and 1921 and again between 1942 and 1964, the US government allowed farmers to recruit Mexican Braceros to fill seasonal farm jobs. A separate guest worker program, H-2 between 1952 and 1986 and H-2A since 1987, is used mostly by farm employers in the eastern states to recruit foreign workers to fill seasonal jobs. US farmers have been asking Congress to relax regulations governing the H-2A program for the past two decades, especially rules that require them to try to recruit US workers, to provide guest workers with free housing, and to pay them a super minimum wage known as the AEWR.

Guest workers change the farm labor market by altering recruitment, remuneration, and retention, with agents handling recruitment in worker countries of origin, guest workers who are aware that termination means losing the right to be in

the US having extra motivation to perform work to the satisfaction of the employer, and retention not an issue because guest workers must leave the US when their jobs end or visas expire. Farm worker unions change the farm labor market in opposite ways. Unions often want a voice in recruitment, and some have tried to operate hiring halls to which employers turn when they need workers. Unions generally favor wage-leveling pay systems and often establish higher-than-minimum wages for the workers covered by the contract. Finally, union contracts usually include seniority and benefit provisions that make it worthwhile for a worker to remain with one farm.

The farm labor market today is at a crossroads. Farm employers and farm worker advocates agree that government policies, especially immigration policies, are likely to shape recruitment, remuneration, and retention. Employers would like more farm workers to be legal guest workers, whereas worker advocates favor legalizing currently unauthorized workers and encouraging farmers to raise wages and take other steps to retain them.

Introduction

Food and fiber is produced on farms in a land-intensive and biological production process by three major types of workers: farm operators, unpaid family workers, and hired workers. Around the world, 59% of the estimated 1.1 billon people employed on farms in 2000 were farm operators and members of their families, and 450 million or 41% are hired or wage workers (Pigot, 2003, p. 38).

The employment of all three types of workers on farms falls with economic development, but the employment of farmers and unpaid family members tends to fall fastest. In the US, hired workers were approximately 60% of average employment on farms in 2010, and farmers and unpaid family members approximately 40%. The consolidation of farms into fewer and larger units that specialize in the production of one or a few crop or livestock commodities promises to further increase the farm worker share of average employment on US farms.

Consolidation of farm production on fewer and larger farms, with hired workers doing an ever rising share of farm work, is occurring around the world. Hired workers do most of the farm work in the production of labor-intensive horticultural crops in Western European countries, and many are migrants from poorer countries, as with Poles employed on German farms, Ukrainians employed on British farms, and Romanians employed on Italian farms. In Japan and Korea, migrants from the Philippines and Vietnam often work on farms that produce labor-intensive crops, as the wives of farmers, as trainees, and as guest workers. In many developing countries, workers from lower wage neighboring countries do much of the work on larger farms and plantations, from Malaysia and Thailand in southeast Asia to South Africa to Costa Rica. This article focuses on the US, which has some of the world's largest labor-intensive farms that hire workers, but the trend toward producing labor-intensive crops on so-called factories in the fields and employing workers who migrate from lower wage areas within their country or another country is universal.

In the US, agriculture is defined for employment purposes in Section 3(f) of the Fair Labor Standards Act (www.dol.gov/whd/regs/statutes/FairLaborStandAct.pdf) as "farming in all its branches…including the cultivation and tillage of the soil, dairying, the production, cultivation, growing, and harvesting of any agricultural or horticultural commodities…the raising of livestock, bees, fur-bearing animals, or poultry, and any practices (including any forestry or lumbering operations) performed by a farmer or on a farm as an incident to or in conjunction with such farming operations, including preparation for market, delivery to storage or to market or to carriers for transportation to market." One practical consequence of this definition is that workers who pack produce on the farm where they work are considered farm workers if the farmer packs only his own fruit. By contrast, farmers who pack their own and other farmers' fruit employ nonfarm workers in what are considered nonfarm operations.

Farm workers (45–2092.02) are defined in the US occupational system ONET as persons who "manually plant, cultivate, and harvest" crops with hand tools that range from hoes to knives. Their job titles include harvester, orchard worker, picker, farm worker, irrigator, and weeder (http://www.onetonline.org/link/summary/45–2092.02). The list of farm worker-related occupations (http://www.onetonline.org/find/quicks=farm+worker) includes agricultural equipment operator (45–2091.00), farm equipment mechanic (49–3041.00), and farm workers who attend to live farm, ranch, or aquacultural animals (45–2093.00).

Hired workers are not spread evenly throughout the US agricultural sector. Almost 500 000 US farms, a quarter, reporting expenses for hired workers in the 2007 Census of Agriculture (COA), but half of these US$26 billion in farm labor expenses, were paid by less than 75 000 producers of labor-intensive fruits, berries and nuts, vegetables, potatoes and melons, and horticultural specialties such as greenhouse and nursery crops (Fruit, Vegetable, and Horticultural speciality (FVH) commodities). Most farm labor expenses were paid by large farm employers in California, Florida, Texas, and Washington, demonstrating that hired farm worker employment is concentrated in three interrelated ways, by commodity, size of farm, and geography.

Hired farm workers, especially those employed on farms producing FVH commodities, are mostly immigrants from Mexico. Before the Immigration Reform and Control Act (IRCA) of 1986, the best evidence suggested that up to a quarter of hired farm workers in southwestern states such as California were unauthorized (Martin *et al.*, 1985). Before IRCA, farmers did not face fines for hiring unauthorized workers, and their distribution in agriculture reflected the risk of losing their workers if immigration authorities drove into fields and checked the legal status of workers. For example, the highest share of unauthorized workers was found in less perishable crops such as citrus. There were fewer unauthorized workers in more perishable leafy green vegetables where producers could lose revenue if their workers were apprehended.

Since the mid-1990s, over half of hired farm workers employed on US crop farms have been unauthorized (Martin, 2009). In contrast to the distribution of unauthorized workers before immigration reform, unauthorized workers today are found throughout the US agricultural sector, including on dairy and other livestock farms that offer year-round jobs. The share of unauthorized workers, approximately 50%, is similar from Vermont dairies and North Carolina vegetable fields to California fruit and vegetable farms.

This article summarizes the characteristics of hired workers employed on US farms. Data are drawn primarily from the US Department of Labor's National Agricultural Workers Survey (NAWS), which has been interviewing 2000–3000 farm

workers a year since 1989 (www.doleta.gov/agworker/naws.cfm). The NAWS was launched to determine if immigration reforms enacted in 1986 contributed to farm labor shortages, and has continued to generate a wealth of information on hired farm workers and their families. The NAWS does not interview workers employed on livestock farms and excludes H-2A guest workers on crop farms.

Farm Employment

In the US and many other industrial countries, hired workers dominate average agricultural employment. During the 1990s, when USDA's National Agricultural Statistics Service (NASS) collected data on farmers, unpaid family workers, and hired farm workers, there were an average 2 million farmers and unpaid family workers and 1.3 million hired workers employed on US farms, meaning that farmers and unpaid family members accounted for 60% of average farm employment.

The employment of all three types of workers on farms have trended downward, but the employment of farmers and unpaid family members fell fastest, so that hired workers were approximately 60% of average employment on farms in 2010. The labor force projections in **Table 1** suggest that the number of farm operators and unpaid family members will continue declining, whereas the number of hired workers stabilizes, so that the share of average employment contributed by hired workers rises to 62% by 2020.

The most detailed source of data on farm employment is from the COA that the US and most other countries conduct periodically (www.agcensus.usda.gov/index.php). In the US, all places that normally sell at least US$1000 worth of farm commodities are surveyed in the years ending in two and seven. Some 482 000 US farms reported almost US$22 billion in labor expenses for workers hired directly by the farm operator in the 2007 COA, and another US$4.5 billion for contract labor, which involves workers brought to farms by labor contractors and other intermediaries. Total labor expenses of US$26 billion were a seventh of farm production expenses.

Farmers reported hiring 2.6 million workers in the 2007 COA, including 35% or 910 000 workers who were hired for 150 days or more on their farms. This 2.6 million jobs-on-farms number must be interpreted carefully because it does not include workers brought to farms by contractors and other intermediaries, and it double counts individuals who are reported by two farmers.

There are several ways to convert the total number of farm jobs into average employment or year-round equivalent jobs in order to compare farm and nonfarm employment. For example, average employment is approximately 1.5 million in US food manufacturing (North American Industry Classification System (NAICS) 311), which means that adding up the employment of wage and salary workers each month in industries ranging from meatpacking to fruit and vegetable freezing and canning and dividing by 12 months generates an average 1.5 million employees. Hired farm workers are not included in the Current Employment Statistics program (www.bls.gov/ces), so their average employment must be estimated.

Average employment of hired workers on farms can be estimated by dividing the farmers' expenditures on hired workers by average hourly earnings to calculate the number of year-round or 2000 h-jobs on farms. The NASS surveys farm employers quarterly to obtain employment and earnings data on hired workers (http://usda.mannlib.cornell.edu/MannUsda/viewDocumentInfo.do?documentID=1063). In 2007, NASS reported that farmers paid hired workers an average US $10.21 an hour, the same year that farmers reported US$26.4 billion in labor expenses. Dividing labor expenses by average hourly earnings, as in **Table 2**, suggests 1.2 million full-time equivalent (FTE) or 2000 h a year jobs on US farms in 2007, about the same as average employment in 2002 using that year's labor expenses and average hourly earnings.

The Quarterly Census of Employment and Wages (www.bls.gov/cew) collects data on the employment and earnings of workers in establishments covered by Unemployment Insurance (UI). The QCEW has several advantages over the COA, including detailed data by commodity and geographic area, but its coverage of farm workers is not complete. All farm workers in

Table 2 US: Hired worker hours, 2002 and 2007

	2002	*2007*
Farm sales (US$billion)	200	297
Labor expenditure (US$billion)	22	26
Sales to expendure ratio	9.1	11.4
Average earns (US$/h)	8.80	10.21

Available at: http://www.bls.gov/opub/mlr/2012/01/ (accessed 04.02.13) and Henderson, R., 2012. Industry employment and output projections to 2020. Monthly Labor Review 135 (1), 65–83. Available at: www.bls.gov/opub/mlr/2012/01/ (accessed 04.02.13).

major farming states such as California and Washington are covered, but workers employed by smaller farm employers in about half the states do not have to participate in UI. The QCEW estimated that 1.2 million of the average 1.4 million hired farm workers in 2011, almost 86%, were covered, reinforcing the estimate that the average employment of hired workers on US farms is 1.2–1.4 million (www.bls.gov/cew/cewbultn11.htm).

There are more farm workers than the average employment of hired workers on US farms because of seasonality and turnover, that is, more than 1.2 million individuals work on farms during a typical year in order to fill peak employment requirements and to account for the fact that many workers are employed less than a full year. During the 1980s, the number of unique individuals employed sometime during the year for wages on farms was 2.5 million, according to supplemental questions attached to the December Current Population Survey (CPS) that generates the unemployment rate each month (Oliveira, 1989).

The CPS farm worker supplement was discontinued, but a count of unique individuals reported by agricultural establishments to UI authorities in California, a state that requires all employers paying US$100 or more in quarterly wages to provide UI coverage to workers, found over two individuals for each year-round farm job in the state (Khan *et al.*, 2004). A two-to-one ratio between farm workers and year-round farm jobs suggests 2.4 million hired farm workers across the US, including 800 000 in California.

Farm Workers: US and Foreign Born

The supply of US farm labor, including the human capital embodied in workers, depends on the decisions of US workers about where to work (approximately 30% of hired crop workers are US born, but almost all new entrants to the farm workforce were born abroad), immigration patterns and the decisions of immigrant workers, and training (two-thirds of US-born crop workers, but only an eighth of the foreign born, completed high school). Hired farm workers are mostly immigrants from Mexico with little education, and most are unauthorized.

The US Department of Labor's NAWS finds a mostly young, Mexican-born, and male crop workforce (www.doleta.gov/agworker/naws.cfm). In recent years, 70% of crop workers were born in Mexico, three-fourths were male, and half were unauthorized. Half of crop workers were under 35 years, two-thirds had less than 10 years schooling, and two-thirds spoke little or no English.

Almost three-fourths of foreign-born workers interviewed by the NAWS are unauthorized, which makes over half of all farm workers illegal, undocumented, or unauthorized. Some 1.1 million unauthorized farm workers were legalized in 1987–88 under the special agricultural workers (SAW) program, and there were four SAWs for each unauthorized worker in the first NAWS survey in 1989.

However, many of the newly legalized SAWs began to leave the farm workforce, so that by 1991 the declining share of SAWs matched the rising share of unauthorized workers. Since the mid-1990s, there have been almost four unauthorized workers for each legalized SAW worker. Unauthorized workers are half of crop workers, but the share of SAWs has declined to less than 10%. The SAW experience suggests that, if there were another legalization of unauthorized farm workers, most would leave farm work within 5 years unless they were required to continue performing farm work (**Figure 1**).

Between 2007 and 2009, almost 30% of crop workers were born in the US and 70% were born abroad, almost always in

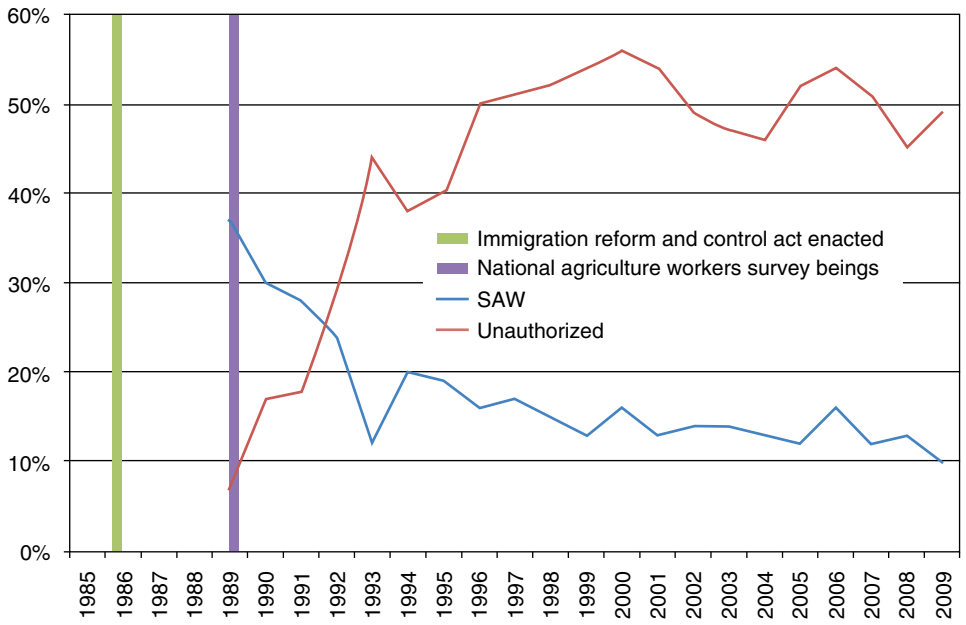

Figure 1 Special agricultural workers (SAWs) and unauthorized crop workers, 1989–2009. Reproduced from NAWS (http://www.doleta.gov/agworker/naws.cfm).

Mexico. Table 2 shows that foreign-born and US-born farm workers were similar in many respects. Their average age was 36–37 years and 77–78% was male. About the same share of foreign-born and US-born workers had incomes below the poverty line, a third of foreign-born families received some means-tested welfare benefit versus a quarter of US-born families, and very few workers were follow-the-crop migrants.

Foreign-born workers differ significantly from the US-born crop workers in legal status, education, and English. For example, 55% of the foreign born are unauthorized, only 13% completed high school, and just 3% spoke English well. Foreign-born crop workers are also more likely than US-born crop workers to be married (Table 3).

The NAWS found that most foreign- and US-born crop workers got their first farm jobs at the age of 22–23 years and had done an average 13 years of US farm work when interviewed. However, foreign-born workers were more likely to be hired by contractors and other intermediaries than US-born workers, 17% versus 2%, more likely to be working in FVH crops, and more likely to be filling harvest jobs, 52% versus 27%. Almost 40% of US-born workers are employed in field crops such as corn and grains, and more than 35% in nurseries.

US-born workers had average hourly earnings of US$9.74 in 2007–09, almost a US$1 an hour more than the average US $8.89 of foreign-born workers. Foreign-born workers had more days of farm work in the past 12 months, 200 versus 180, and were less likely to have health insurance provided by their current farm employer. A seventh of foreign-born workers, versus a quarter of US-born workers, had employer-provided health insurance in their current job.

More than three-fourths of foreign-born workers, and two-thirds of US-born workers, plan to continue working in agriculture for at least five more years. A third of the foreign-born, versus two-thirds of the US-born, say they could find a nonfarm job within a month.

Table 4 examines two groups of farm workers whose share of crop workers changed over time. SAW-legalized farm workers, including a few workers legalized under the general legalization program in 1987–88 and Central American programs in the 1990s, fell from 32% of all crop workers to 15% between 1989–91 and 1998–2000; the share of SAWs has since stabilized at just more than 10%. Foreign-born newcomers, who are workers in the US less than a year before they were interviewed, rose sharply during the 1990s to almost a quarter of all crop workers in 1998–2000. Since then, the share of newcomers has fallen to less than 10% between 2007 and 2009.

As would be expected, SAW-legalized workers are much older than newcomers, as they had to do farm work as unauthorized foreigners in 1985–86 to qualify for legalization. The average age of SAW-legalized workers was 49 in 2007–09, versus 25 for newcomers. Three-fourths of the SAW-legalized workers did not move, but a quarter returned to Mexico in the past year, usually over the Christmas holidays. More than 90% of the newcomers to the US farm workforce moved from Mexico to the US in the year before they were interviewed.

SAW-legalized workers are older and have less education than foreign-born newcomers, on average 5 versus 6 years (7% of both groups had graduated from high school in 2007–09), but are much more likely to speak some English and to have incomes above the poverty line. By contrast, approximately 95% of foreign-born newcomers had below-poverty level incomes. A third of foreign-born newcomers were employed by labor contractors, versus less than a fourth of SAW-legalized workers, including only an eighth in 2007–09. Foreign-born newcomers had fewer days of farm work than SAW-legalized workers, in part because not all were in the US for the full year before being interviewed.

Approximately 90% of both SAW-legalized and foreign-born newcomer workers are employed in FVH commodities, a pattern that has not changed over the past two decades. The share of both SAW-legalized and foreign-born newcomer workers filling harvest and postharvest jobs has been falling, and was half or less in 2007–09.

SAW-legalized workers earned an average 1.5 times the federal minimum wage in 1989–91, but their average premium over the minimum wage fell in the subsequent periods. Foreign-born newcomers earned a 30% premium over the federal minimum wage in 1989–91, and they averaged only 10% above the federal minimum wage in 2007–09. A third of SAW-legalized workers, but only an eighth of newcomers, believe they could get a nonfarm job in a month.

In a hired farm workforce that involves 2.5 million individuals working for wages on US farms sometime during a typical year, making the hired farm workforce equivalent to the average employment of janitors and cleaners, farm worker averages can obscure important changes. For example, almost all foreign-born farm workers were born in Mexico, but

increasingly in southern rather than west-central Mexico where Braceros were recruited between 1942 and 1964 (Martin, 2009). Some Spanish-speaking west-central Mexicans have become supervisors of newly arrived indigenous workers from southern Mexico who may not speak Spanish well, reflecting the growing complexity of the hired farm workforce (Mines, 2010).

Immigration Reform and Farm Workers

The NAWS has found a more stable hired farm workforce in recent years. In recent years, the average age of workers has increased, workers are obtaining more days of farm work, and more say they plan to remain farm workers longer than the usual 10 years. The share of more-than-10-year workers rose from 30% in 1999–2000 to 45% in recent years, which may reflect more difficulties finding nonfarm jobs as a result of the 2008–09 recession and fewer new newcomers due to stepped up border controls that encourage farm employers to raise wages and make more efforts to retain current workers.

The NAWS found rising average hourly earnings, as reported by workers, from approximately US$6.70 in 1999–2000 to US$9.40 in 2009–10, up 40% (nominal) and 16% in real terms. Annual farm worker earnings rose as well. The NAWS collects farm worker income in categories, and approximately 40% of farm workers reported US$5000 to US $15 000 in farm earnings in 1999–2000, compared with 35% in 2009–10. Meanwhile, the share of workers earning more than US$20 000 rose from less than 5% to approximately 25% over the past decade.

However, half of crop and nursery workers remain unauthorized, helping to explain the keen interest of farm employers in immigration reforms that could lead them to fire experienced but unauthorized workers to avoid fines unless their currently unauthorized workers were legalized. The prospect of new requirements that employers use the Internet-based E-Verify system to check the legal status of newly hired workers has encouraged most farmers to demand easier access to legal guest workers to fill farm jobs. However, there is not yet any agreement on a package of new measures to keep unauthorized workers from getting US jobs and allowing farm employers to more easily hire guest workers.

Dealing with Illegal Immigration

The US is a nation of immigrants. The US Presidents frequently use the phrase "e pluribus unum" to remind Americans that they share the experience of themselves or their forebears leaving another country to begin anew in the US. Immigration is widely believed to serve the US national interest, as immigrants better themselves while enriching the US (Martin and Midgley, 2006).

The major immigration issue for the past quarter century has been what to do about illegal immigration. The US had 40 million foreign-born residents in 2010, including 11 million, approximately 30%, who were illegally present (Martin and Midgley, 2006). Public opinion polls find widespread dissatisfaction with illegal immigration, showing that most Americans believe that the federal government should do

more to reduce illegal immigration. For example, a CNN/ORC poll in November 2011 found 55% of respondents supported deporting unauthorized foreigners in the US, whereas 42% would offer them a path to legal residence (www.pollingreport.com/immigration.htm).

Disagreement over what to do about illegal migration has stymied immigration reform for the past two decades. After the mid-1990s farmers acknowledged that half of their workers were unauthorized and tried to persuade Congress to make it easier for them to employ legal guest workers, but President Clinton in June 1995 made a statement that blocked their efforts, saying: "I oppose efforts in the Congress to institute a new guest worker or 'bracero' program that seeks to bring thousands of foreign workers into the US to provide temporary farm labor." (Martin, 1998).

Neither farm employers nor worker advocates knew what would happen in the 2000 elections. However, the election of President Vicente Fox in Mexico, who made a Mexico–US guest-worker program his top foreign policy priority, prompted them to negotiate the Agricultural Jobs, Opportunity, Benefits and Security Act (AgJOBS) in Fall 2000 (Martin, 2005). AgJOBS would repeat of the 1986 approach to unauthorized farm workers, viz, legalize currently unauthorized farm workers and make it easier for farm employers to hire legal guest workers.

Farm employers and worker advocates joined a coalition of groups advocating comprehensive immigration reforms with three prongs, more enforcement to deter unauthorized migration, legalization for unauthorized foreigners in the US, and new guest worker programs. The Mexican government pressed President George W. Bush to endorse comprehensive immigration reform and Mexico's then Foreign Minister Jorge Castaneda laid out a four-pronged reform agenda in June 2001 that included legalization, a new guest-worker program, reducing border violence and exempting Mexico from visa quotas, and concluded: "It's the whole enchilada or nothing." Fox was visiting Bush in Washington DC and pressing for this 'whole enchilada' immigration reform just before the 11 September 2001 terrorist attacks.

The terrorist attacks pushed immigration reform into the background, but after the unemployment rate dropped below 6% in 2003 and some employers complained of labor shortages, the stage was set for a debate. Congress tackled immigration in 2005, 2006, and 2007, at the height of the housing boom. The Republican-controlled House moved first, approving an enforcement-only bill in December 2005 that would have required all employers to participate in a federal program now called E-Verify that allows employers to check the legal status of new hires against government databases. The House bill also called for hiring more Border Patrol agents and building a fence along a third of the 2000 mile Mexico–US border and would also have defined 'illegal presence' in the US a felony, making it harder for unauthorized workers to become legal guest workers and immigrants in the future.

Reaction against this so-called 'Sensenbrenner bill' culminated in a 'Day Without Immigrants' 1 May 2006 that saw some meatpacking plants, home builders, and restaurants close for the day as more than a million protestors took to the street and called for a path to legalization for unauthorized foreigners in the US. These demonstrations were cited as the Democratic-controlled Senate approved the Comprehensive Immigration Reform Act (CIRA) in May 2006. Like the Sensenbrenner bill, CIRA would have required employers to submit data on all new hires to a government database and added fences and Border Patrol agents. However, instead of defining unauthorized foreigners as felons, CIRA would have allowed them to earn a legal immigrant status by paying fees and taxes and learning English (Martin, 2006). CIRA, whose supporters included Senators Edward Kennedy (D-MA) and John McCain (R-AZ), would have created a new guest worker program that adjusted admissions to employer requests for guest workers.

When the Senate tackled immigration reform again in 2007, it was unable to approve a revised version of CIRA despite the active support of President Bush. Republicans who opposed 'amnesty' and Democrats who feared that more guest workers would hurt US workers combined to defeat CIRA (Migration News, 2007a). In response, the Bush administration stepped up raids of workplaces with unauthorized workers, such as the one at Agriprocessors in Postville, Iowa, that resulted in the arrest of approximately 400 workers in May 2008. The Department of Homeland Security worked with the Social Security Administration to include with the no-match letters that SSA sends to employers who submit data on 10 or more workers whose name and number do not match SSA records a notice to inform employers they would be considered to have knowingly hired unauthorized workers if they continued to employ workers for whom SSA had identified discrepancies (Migration News, 2007b). Farm employers feared that they would have to risk fines for knowingly hiring unauthorized workers in order to get their crops picked.

There was little willingness to tackle immigration reform during the recession that began late in 2007 and the presidential elections of 2008. President Obama supported comprehensive immigration reform during the campaign, but stepped up enforcement at the border and inside the US to prove to skeptics that the federal government could reduce illegal migration. During Obama's first 4 years, the Mexico–US fence was extended to a third of the 2000 mile Mexico–US border and the number of Border Patrol agents increased to more than 20 000. These enforcement efforts and the US recession combined to reduce apprehensions of foreigners just inside the US border to 340 000 in FY11, the lowest number since the early 1970s (Migration News, 2012b).

Obama's interior enforcement strategy has been more controversial. DHS stopped workplace raids in 2009 and launched I-9 audits that involve checking the forms completed by newly hired workers and their employers. These so-called silent raids have DHS agents telling employers which of their employees appear to be unauthorized and asking employers are to notify these employees and ask them to clean up the discrepancies in their records or terminate them. For example, Gebbers Farms in Brewster, Washington, a 5000-acre apple and cherry operation north of Wenatchee, wound up terminating 550 workers in 2010, almost half of its workers, after an I-9 audit (Rural Migration News, 2010b).

The recession and heath care dominated domestic policymaking in recent years, and legislative action to deal with unauthorized migration shifted to the states. Beginning with Arizona, more states have been enacting laws that require

employers to use the federal government's E-Verify system to check the legal status of new hires and to have state and local police check the legal status of persons they encounter during traffic stops and other interactions (Martin, 2012). The US Supreme Court, which upheld Arizona's Legal Arizona Workers Act in May 2011 requiring employers to participate in E-Verify, is expected to rule soon on the Support Our Law Enforcement and Safe Neighborhoods Act (SB 1070) enacted in 2010.

Other states followed Arizona, enacting laws to reduce illegal immigration by requiring employers to participate in E-Verify and to have the police to check the legal status of persons they encounter. In 2011, Alabama, Georgia, Indiana, South Carolina, and Utah enacted such laws, prompting the US Department of Justice to sue to block these laws from going into effect by arguing that these state laws were an unconstitutional infringement on the federal government's authority to establish immigration policy. Federal judges blocked implementation of most sections of the immigration control laws of Arizona, Georgia, and South Carolina, but not those of Alabama. The US Supreme Court in June 2012 maintained many of these injunctions that prevented state immigration control laws from going into effect, but allowed provisions that require state and local police to determine the status of persons they 'reasonably suspect' are not lawfully in the US to be implemented. Some farmers allege that state immigration control laws discourage farm workers from coming to or staying in their states.

Immigration Reforms and Farm Workers

Farm employers and worker advocates have been active participants in the immigration reform debate. During the first attempt to deal with illegal migration in the IRCA of 1986, farm employers and worker advocates eventually agreed on a compromise that legalized unauthorized farm workers who had done at least 90 days of farm work in 1985–86 and made employer-friendly changes to the then agricultural guest worker program, whose name was changed from H-2 to H-2A (Martin, 1994).

Farm labor costs were expected to rise after enactment of IRCA as farmers raised wages to retain legalized workers or built housing to employ H-2A guest workers. Instead, illegal immigration continued and unauthorized workers used false documents to get hired. As the employers do not have to determine the authenticity of the documents presented by newly hired workers, they were not liable if the workers were later found to be unauthorized. Immigration reform thus contributed to the spread of unauthorized workers throughout the US agriculture sector (Martin *et al.*, 1995).

There were few complaints of farm labor shortages in the 1990s. Farm employers aware that a rising share of their workers were unauthorized, pushed for employer-friendly changes to the H-2A program, and new guest worker programs, but President Clinton threatened to veto any new guest worker program, and none was enacted. For example, Rep Richard Pombo's (R-CA) bill to grant temporary work visas to 250 000 foreign farm workers who could 'float' from farm to farm was defeated by the House in March 1996 (Rural Migration News, 1996).

In Fall 2000, worker advocates and farm employers negotiated AgJOBS to repeat the IRCA approach to unauthorized migration and agriculture, viz, legalize the current unauthorized farm wrokers and make it easier for farm employers to hire legal guest workers in the future. AgJOBS included several important changes. Like the SAW legalization program, AgJOBS would allow currently unauthorized farm workers to legalize their status immediately. However, to 'earn' a regular immigrant status for themselves and their families, foreigners legalized under AgJOBS would have to continue to do farm work, a provision aimed at preventing an immediate exodus of newly legalized farm workers to nonfarm jobs (Martin, 2009).

There have been several iterations of AgJOBS. The most recent version, S 1038 and HR 2414 introduced in May 2009, would have allowed up to 1.35 million unauthorized farm workers who did at least 150 days or 863 h of farm work in the 24-month period ending 31 December 2008 to apply for Blue Card probationary status (Rural Migration News, 2009a). Blue Card holders could work and travel freely within the US and enter and leave the US, and could earn an immigrant status for themselves and their families by continuing to do farm work over the next 3–5 years. AgJOBS has three continued farm work options: (1) performing at least 150 days (a day is at least 5.75 h) of farm work a year during each of the first 3 years after enactment; (2) doing at least 100 days of farm work a year during the first 5 years; or (3) working at least 150 days in any 3 years, plus 100 days in the fourth year (for workers who do not do 150 days in the first 3 years).

For 6 years, farm employers of Blue Card holders would have to provide their employees with written records of their farm work and submit a copy to DHS or face fines of up to US $1000. DHS would check documentation of the farm work of Blue Card holders and, after they paid fees and fines, Blue Card holders and their family members could become immigrants.

AgJOBS would change the H-2A program in three major ways to make it easier for farmers to recruit and employ legal guest workers (Rural Migration News, 2009a). First, farm employers could attest that they need guest workers and are paying prevailing wages rather than have Department of Labor (DOL) supervise their efforts to recruit US workers, a process called certification. Attestation would effectively shift control of the border gate from the US Department of Labor to employers.

Second, rather than provide free housing to H-2A and out-of-area US workers as is required currently, AgJOBS would allow farm employers to pay a housing allowance of US$1–2 an hour, depending on the local costs to rent two-bedroom units that are assumed to house four workers, if state governors certified that there is sufficient rental housing for the guest workers in the area where they will be employed. Third, the Adverse Effect Wage Rate (AEWR), the minimum wage that must be paid to legal guest workers, would be frozen at last year's levels and studied, effectively reducing the AEWR by US $1–2 an hour and offsetting the cost of the housing allowance.

Despite bipartisan support, AgJOBS has not been enacted. Meanwhile, farmers aware that (1) half of their workers are unauthorized, (2) federal I-9 audits of their employment records can remove a large share of their workers, and (3) more states are enacting laws requiring employers to use E-Verify

express worries about obtaining new and replacement workers, worry that they could lose a large share of their workers suddenly to federal or state enforcement. Farmers are especially fearful of requirements to participate in the E-Verify program, which involves submitting data on newly hired workers to a federal database and learning instantly if the worker is authorized to be employed in the US.

The House Judiciary Committee in September 2011 approved the Legal Workforce Act (HR 2164) to phase in E-Verify for all US employers over 4 years. Farmers oppose a federal requirement to check the legal status of newly hired workers unless it is accompanied by employer-friendly changes to the H-2A guest worker program or a new program. A requirement that all farm employers participate in E-Verify without a new guest worker program, farmers argue, means labor shortages and crop losses, as allegedly occurred in Alabama and Georgia after state immigration control laws went in effect in 2011. Several House Republican proponents of mandatory E-Verify introduced proposals for new guest worker programs in Fall (2011), but they were not acted upon (Rural Migration News, 2011).

Recent years have generated record net farm income and rising land prices. Despite fears of more enforcement, farmers have not yet changed crops to avoid the need to hire workers. If there is market demand, farmers are planting more despite fears of labor shortages, as with strawberries, where acreage doubled between 1990 and 2010 (Calvin and Martin, 2010). However, fears of labor shortages and disruptions make farm employers well aware of the three major immigration options that could affect the future availability of farm workers, viz, *status quo*, enforcement and guest workers, and comprehensive reform.

A continuation of the status quo would mean that about half of farm workers remain unauthorized, that federal I-9 audits and state laws disrupt employment and hiring unevenly, and that farm employment shifts toward the extremes, to intermediaries willing to absorb the risk of enforcement and toward investment in housing in order to employ H-2A guest workers. New entrants to the farm workforce would continue to grow up outside the US, and enter the US illegally to do farm work or enter legally as guest workers. Unauthorized workers fired after I-9 audits or not hired because their employer participates E-Verify typically remain in the US and move on to another employer, so the status quo is likely to promote worker circulation that limits employer training of workers and worker advancement on particular farms.

The second option is stepped-up enforcement and new or revised guest worker programs. More federal enforcement and state immigration control laws could be coupled with new guest worker programs or revisions to the current H-2A program that include the revisions in AgJOBS, viz, no DOL-supervised recruitment of US workers, no requirement to provide housing for guest workers, and a lower minimum wage for guest workers. Several of the proposals made by and on behalf of farm employers would shift the administration of new or revised guest worker programs from the US Department of Labor to the US Department of Agriculture. Farm worker advocates oppose these so-called E-Z guest worker proposals.

The third option is comprehensive immigration reform that deals with all unauthorized foreigners in the US, the 1 million employed in agriculture and the 7 million employed in nonfarm jobs, as well as their 3 million dependents. Comprehensive immigration reform has three major components: enforcement, legalization, and guest workers, but the details of each component, and an assessment of how they could interact, makes enactment difficult. For example, how should employer participation in E-Verify be phased in, and should farm employers be exempt from having to recheck the legal status of returning seasonal workers? Should there be a separate legalization for unauthorized farm workers, and should it require farm workers to want to earn and immigrant status to continue to do farm work, or would any US work suffice to earn an immigrant status? Finally, what new guest worker program can balance the interest of farmers in having sufficient seasonal workers while protecting farm workers?

Farmers and Farm Workers

Most US farm operators are older US-born white men, whereas most hired farm workers are younger immigrant Hispanic men. The median age of all US workers is 41 years; the median age of farm operators is late 50s, and the median age of hired farm workers is less than 30 years. Farming is a multigenerational career for many farm operators but a less-than-a-decade job for most hired workers.

The US has what has been called an 'apartheid farm work force' of mostly older, white, and US citizen farm employers and mostly young, Hispanic, and foreign-born hired workers. If current trends continue, new hired workers will continue to be born outside the US, whereas future farmers will be born in the US.

Hired Hands versus Hired Workers

Thomas Jefferson, an agrarian fundamentalist who believed that family farming would preserve democracy and respect private property as they farm the land they owned averred that: "those who labor in the earth are the chosen people of God." In a country offering free land, Jefferson did not believe that the US would have a permanent class of hired farm workers. Instead, he considered farm workers to be youthful 'hired hands' who lived and worked temporarily alongside the farmer before climbing the agricultural ladder from farm worker to farm operator (Martin, 2003, Chapter 2).

This worker-to-farmer mindset helps to explain why hired workers were initially excluded from federal labor laws during the 1930s. During Congressional debates on the federal minimum wage and other labor laws, it was frequently asserted that farmers and farm workers had the same interests in higher crop and livestock prices, making employer–employee relationships in agriculture different from those in the factories affected by labor laws and unions (Martin, 2003, Chapter 3). There was always more myth than reality to the agricultural job ladder, especially in California, and it became clearer during the 1930s, when Dust Bowl migrants who migrated to California found large and specialized farms that hired crews of seasonal workers when needed. Dust Bowl migrants, English-speaking US citizens, and their presence prompted

many studies of farm workers while inspiring John Steinbeck's epic novel, 'The Grapes of Wrath.'

Farm labor reformers during the 1930s were divided about how government should respond to the system of large and specialized farms that relied on armies of low-skilled seasonal farm workers that had evolved in the western states. Economist Paul Taylor wanted to break up large farms into smaller family-sized operations, fulfilling Jefferson's dream, while lawyer Carey McWilliams believed that California agriculture would continue to be dominated by 'factories in the fields' and wanted to extend factory labor laws to large farms (Martin, 2003, Chapter 2). The fact that most US farms were operated by families, the divisions between farm labor reformers on appropriate policies, and the outbreak of World War II that enabled many Dust Bowl migrants to find nonfarm jobs combined to reduce the urgency of dealing with farm labor issues. Instead, Mexican Bracero farm workers were admitted to the US beginning in 1942, and their presence influenced wages until the Bracero program ended in 1964 (Martin, 2003, Chapter 2).

Farm workers, who were initially exempt from social security, UI, and minimum wage laws, are now protected under most federal labor laws, although sometimes at different levels, as with overtime pay, which is applicable to farm workers only after 10 h a day and 60 h a week in California, versus 8 h and 40 h for nonfarm workers. Farm workers continue to be excluded from the National Labor Relations Act (NLRA), which governs the union organizing and bargaining in the private sector, although farm workers in California have more rights under the state's Agricultural LRA than they would have under the federal NLRA.

Most of the largest farm employers around the US are covered by most federal labor laws, and the majority of farm workers are in states such as California and Washington that have eliminated most labor law exemptions for agriculture. California has been a leader in enacting special laws to protect farm workers, including from heat stress. Since 2005, farm employers must make available at least a quart of water per worker per hour, provide access upon request to shade for at least 5 min to workers suffering from heat illness, and ensure that shade is available for up to a fourth of the workers when the temperature exceeds 85 °C. Employers must train their workers and supervisors about heat illness, monitor new hires, and have a written plan to deal with workers suffering from heat illness (Rural Migration News, 2008).

Many farm–nonfarm differences in labor laws have been eliminated, but agriculture remains what has been called an 'American apartheid' industry. There may be no other US industry in which most employers are older white US citizens and most hired workers are young Hispanic immigrants. Many of the Hispanic immigrants are from rural Mexico, and many would like to move up the agricultural job ladder in the US from farm worker to farmer. However, the job pyramid in agriculture is steep, offering relatively few opportunities for those who begin as seasonal workers to move up to year-round jobs in agriculture and eventually to farm operators.

The inability of most farm workers to climb the agricultural ladder to farm operator means that the best way to assist most seasonal farm workers is to help them to find nonfarm jobs. The best way to help the children of farm workers to achieve higher incomes than their parents is to provide education so that they can find nonfarm jobs. The federal government's Migrant and Seasonal Farm Worker (MSFW) assistance programs, launched during the 1960s when farm worker wages were rising rapidly after the end of the Bracero program, aimed to help MSFWs and their children 'escape' from (mostly seasonal) farm jobs (Martin and Martin, 1993).

Most farm workers seeking upward mobility find it easier to move out of agriculture rather than move up the job ladder in agriculture, and their children educated in the US rarely follow their parents into seasonal farm work. There are many reasons why most hired farm workers find it hard to move up in agriculture, including limited access to capital in the capital-intensive FVH sectors of agriculture where most farm workers are employed, low educational and language attainment, and a lack of agriculture-specific expertise, for example, in cooling and marketing perishable commodities.

Climbing the Agricultural Job Ladder

The commodities with the most common movement from worker to operator include strawberries, where most of those making the transition bring only their own labor to newly established farming operations. Many smaller strawberry growers lease land and plants from a cooler and marketer, whose field man tells them when to irrigate and fertilize. Small strawberry growers are contractually required to harvest and deliver their berries to the cooler, who deducts the cost of any loans and selling costs from revenue before sending the balance to the grower.

By some estimates, two-thirds of California strawberry growers are Latinos, many of whom used to be pickers. Most Latino berry growers have only a few acres, so they farm much less than two-thirds of the approximately 40 000 acres of California strawberries. The high share of Latino growers may help to explain the low earnings of berry pickers, which are the lowest of any commodity in California, an average US$10 an hour in 2010 when the average for California agriculture was US$11.62. Indeed, average earnings in strawberries were less than the US$10.50 an hour paid to employees of labor contractors.

Strawberries farming is very labor-intensive, requiring an average 1.5–2 workers per acre (Rural Migration News, 2009b). However, they also generate high revenues of US $40 000–US$60 000 an acre, so that even a 5-acre operation can have up to 10 employees and up to US$300 000 in annual revenue. Small farmers often have difficulty managing cash flow when workers must be paid weekly but marketers pay farmers every few weeks, prompting some researchers to conclude that small Hispanic strawberry growers are essentially sharecroppers for the marketers (Wells, 1996). A few worker-to-strawberry-farmers have been successful, but many struggle and some revert from farm operator to hired worker.

It may be easier for immigrant workers in year-round jobs in smaller dairies and nurseries to climb the agricultural ladder from worker to farmer, as year-round workers often live on dairy farms and work alongside their employers every day. Some of the farmers who get to know and trust year-round workers may finance their transition from worker to operator; however, there are few examples of such farmer-financed

transfers of operations to hired workers. Alternatively, there may be an evolution toward fewer and larger farms that rely both on hired managers and hired workers. If pension and insurance funds continue to buy land and rely on farm management firms to farm it, there may be more rather than fewer layers between seasonal farm workers and the beneficiaries of their work.

A system of large farms with hired managers and hired workers may embrace the adage that 'agriculture is different' and requires a foreign-born workforce to fill especially seasonal jobs. If the government were to embrace the notion that the hired farm workers of tomorrow are growing up today somewhere outside of the US, the focus of policy debates might shift from whether immigrant farm workers are necessary for US agriculture to how they should be admitted and managed.

The 'agriculture is different' mantra is repeated frequently in debates over immigration reform and agriculture. Senator Charles Schumer's (D-NY) asserted that "even if [farm employers] offer Americans twice or sometimes three times the minimum wage and provide benefits, American workers simply won't stay in these [farm] jobs for more than a few days." (Rural Migration News, 2011) Senator Dianne Feinstein (D-CA) said: "I think a country that's strong really should be able to produce its own food, but you can't do it with domestic labor, and that's just a fact." (Rural Migration News, 2010a).

The US government has been unwilling to make an explicit agriculture-requires-foreign-workers statement. Instead, the government has continued past policies of allowing farmers who anticipate labor shortages to request permission to employ H-2A guest workers. There will be an ongoing debate over how many hurdles employers must surmount before they can employ the foreign workers they prefer that is fueled on the one hand by reports of labor shortages that lead to crop losses and on the other by reports of abused workers.

Farm Wages and Food Costs

What does the debate over farm workers, farm structure, and immigration reform mean for consumers? The answer is surprisingly little, as US consumers spend relatively little on food eaten at home, farmers get less than a third of retail food spending, and farm workers get less than a third of farm revenue.

The US Bureau of Labor Statistic's Consumer Expenditure Survey reported that there were 122 million 'consumer units' in 2011 with an average of 2.5 persons, 1.3 earners, and 1.9 vehicles. Average consumer unit income before taxes was US $63 700 and average annual expenditures US$49 700 (www.bls.gov/cex).

These consumer unit or household expenditures included US$6460 for food, approximately 13% of average spending. Food spending was divided between food consumed at home, US$3800 or 58% of food spending (US$73 a week), and food bought eaten from home, US$2600 or 42% of food spending (US$50 a week). The cost of food away from home largely reflects convenience, service, atmosphere, and other factors not related to food costs. For example, a rule of thumb is that food costs are approximately 35% of the price of food in cafeteria-style restaurants, 30% of the consumer price in fast food, and 25% in fine dining.

To put food spending in perspective, consumer units or households spent far more on other items. For example, spending on housing, US$16 800, was almost three times more than spending on food, and spending on transportation, US$8300, exceeded spending on food. Consumer unit or household spending on health care, US$3300, and entertainment, US$2600, almost matched spending on food.

Most analyses of farm worker wages and food costs are limited to spending for food consumed at home. The largest food-at-home expenditures were for items in which farm worker wages are a small share of retail prices, including meat and poultry, for which consumer units or households spent an average US$832 or US$16 a week. Expenditures on cereal and bakery products, US$531, exceeded the US$407 spent on dairy products.

Farm worker wages loom largest in the prices of fresh fruits and vegetables, but consumers spend relatively little on them. Average consumer unit or household spending on fresh fruits were US$247 in 2011, and on fresh vegetables US$224, for a total of US$471, or US$9 a week, plus an additional US$116 spent on processed fruits and US$128 spent on processed vegetables. The average consumer unit spent almost as much on alcoholic beverages, US$456 in 2011, as on fresh fruits and vegetables, US$471. Farmers get a small share of the retail food dollar, more for meat and dairy products and less for wheat and grains. Farmers received an average 28% of the retail price of fresh fruits in 2009, and 25% of the retail price of fresh vegetables, so consumer expenditures of US$471 on these items meant US$125 to the farmer (www.ers.usda.gov/Briefing/FoodMarketingSystem/pricespreads.htm).

Farm labor costs are typically less than a third of farm revenue for fresh fruits and vegetables, meaning that farm worker wages and benefits for fresh fruits and vegetables cost the average consumer unit US$41 a year. Consumers who pay US$2 for a pint of strawberries are giving 56 cents to the farmer and less than 20 cents to the farm worker; those spending US$2 for a head of lettuce are giving 50 cents to the farmer and 15 cents to the farm worker.

If farm wages rose, what would happen to consumer expenditures on fresh fruits and vegetables? In 1966, the United Farm Workers union won a 40% wage increase for some table grape harvesters, in part because the Bracero program that brought Mexican workers into the US ended in 1964. The average earnings of field workers were US$10.33 an hour in 2011, so a 40% wage increase would raise average hourly earnings to US$14.46 an hour. If this wage increase were fully passed on to consumers, the 15–20-cent farm labor cost of a pint of strawberries or head of lettuce would rise to 20 to 28 cents, and the retail price would rise from US$2 to US$2.08.

What would a sharp increase in farm wages mean for a typical household? A 40% increase in farm labor costs translates into a 3.6% increase in retail prices. This relatively small jump in retail prices is due to two major factors: the small farm share of retail prices and the small share of farm worker wages in farm revenues. If farm wages rose 40%, and the wage increase were passed fully to consumers, average spending on fresh fruits and vegetables would rise by approximately US$17

a year. However, the average earnings of seasonal farm workers, now approximately US$10 000 a year, would rise to more than US$14 000 a year, or from below the 2011 poverty line of US$10 890 for an individual to above the line.

Food Processing and Meatpacking

Food manufacturing (NAICS 311) employed an average 1.4 million workers in 28 500 establishments in 2010. Average weekly wages were US$780, or 70% of the average US$1100 a week in manufacturing. Average weekly earnings tend to fall as employment rises in food manufacturing, so that workers in small sectors, such the 59 000 employed in grain and oil seed milling (NAICS 3112) earned an average US$1000 a week, whereas workers in larger sectors such as fruit and vegetable preserving (NAICS 3114) earned an average US$810 a week.

The largest food manufacturing subsector is animal slaughtering and processing (NAICS 3116), which employed 486 000 workers in 2010, a third of food manufacturing employment, to turn cattle, hogs, sheep, and poultry into meat and other products. Meatpacking wages averaged US$630 a week, approximately 77% of the average in food manufacturing and 57% of the average earnings of all manufacturing workers. Approximately 60% of meatpacking workers are in rural areas, making animal slaughtering and processing the largest manufacturing employer in rural America.

Meatpacking has changed over the past three decades from a mostly urban to a mostly rural industry in response to a search for cost savings and innovations such as preparing retail cuts of meat in meatpacking facilities. Average hourly meatpacking earnings, which were similar to wages in durable manufacturing sectors such as autos in the 1970s, are today about half the average manufacturing wage of US$24 an hour. Large plants in small towns can change their demography quickly, which has sometimes led to tensions as residents complain of non-English speaking residents. On the contrary, some local residents benefit by renting housing or selling food to newcomers in towns that were often losing population.

Meat processing is a nonfarm industry critical to US agriculture. Livestock and products account for half of annual farm sales, and cattle, hogs, and broilers account for two-thirds of livestock sales. Red meat production has been rising, from 46 billion pounds in 2000 to 49 billion pounds in 2010, whereas poultry meat production rose from 36 billion pounds to 43 billion pounds in the same period. Exports of beef, pork, and poultry rose from 9 billion pounds in 2000 to 14 billion pounds in 2010, whereas imports fell from 4 billion pounds to 3.4 billion pounds. The US has a significant trade surplus in meat.

From Urban to Rural

Meat processing has changed in scale and location, so that today there are fewer and larger farms, feedlots, and meat processors, reflecting a general consolidation in US agriculture and manufacturing. Meat production in the 1960s and 1970s shifted from urban areas near the consumers of meat products to rural areas nearer cattle and poultry producers, as from Chicago to Garden City, Kansas (MacDonald and Ollinger, 2000).

The share of meat processing employees in nonmetro areas rose from less than half in 1980 to 60% by 2000, and many of the new plants in rural areas are larger than the older urban plants they replaced. More than 85% of US beef, pork, and chicken are from large plants that process at least 500 000 cattle, a million hogs, and several million chickens a year, and most have more than 400 employees. Meat products are usually transported from the plants to supermarkets and other outlets in refrigerated trucks.

The shift of meatpacking from urban to rural areas was prompted by several factors, including lower land and labor costs in rural areas, less stringent environmental restrictions, and easier access to animals. Lower labor costs in rural areas encouraged urban supermarkets paying high wages to butchers to request preparation of meat products that were ready for sale to consumers at the processing plant, so that boxed, vacuum-packed, and cut-up and sometimes cooked and seasoned meat products are now prepared in processing plants. Retail packages of meat rather than carcasses have become the primary output of the plants. One summary concluded that meatpacking work is "hard and dangerous, and wages are low by manufacturing standards, although often high compared with alternative employment in the rural communities in which plants are concentrated." (Craypo, 1994, p. 85).

The meat processing industry has four major segments, animal slaughtering (NAICS 311611), meat processed from carcasses (311612), rendering and meat byproduct processing (311613), and poultry processing (311615). Poultry processing has about as many employees as meat processing, but meat wages are typically higher than poultry wages because more of the meat plants are in higher-wage midwestern states, whereas poultry processing is mostly in lower-wage southern states.

The poultry processing developed later than meatpacking, but became the first vertically integrated meat industry, meaning that poultry processors supply chicks and feed to farmers who own the buildings and supply the labor to raise the chickens. Almost all US broilers are raised under contracts with processors. The cattle industry is least vertically integrated, in part because it has two distinct segments. Mostly small feeder cattle operations raise calves and sell them to generally larger feedlots that 'finish' the cattle. The more concentrated poultry industry has been associated with falling costs and rising consumption of poultry products.

Meatpacking is one of the most dangerous manufacturing jobs in the US, with injuries that include muscular trauma, repetitive motion disease, cuts, and strains. The Bureau of Labor Statistics (www.bls.gov/iif) conducts an annual survey of workplace injuries and reports an incidence rate, the number of injuries and illnesses reported per 100 full-time equivalent workers. In 2010, some 3.1 million nonfatal workplace injuries and illnesses were reported by private industry employers, an incidence rate of 3.5 reportable injuries per 100 equivalent full-time workers. The rate was 4.4 for manufacturing, 5.8 for food manufacturing, and more than 10 in animal slaughtering and processing.

Historically, most meatpacking workers outside the southern states were represented by unions that had master agreements with the largest packers. Union strength peaked in

1968, when more than 90% of meat production workers belonged to unions and the average meatpacking wage of US $3.45 an hour was 15% above the average manufacturing wage of US$3 an hour (Craypo, 1994, p. 71). During the 1980s, many of the unionized plants in urban areas closed amidst a wave of strikes to protest requests for wage concessions. By 1986, average meatpacking wages of US$8.24 an hour were 18% below the average manufacturing wage of US $9.75. Meatpacking wages continued to fall, and by 1990 the US$8.73 an hour wage was 24% below the US$10.85 average manufacturing wage (Craypo, 1994, p. 71).

Meatpacking Workers

Meatpacking has long attracted workers with relatively little education and sometimes little English, but meatpacking wages were comparable to those of other manufacturing industries when meat processors were in urban areas. Few meatpacking workers followed plants from urban to rural areas, so when the industry moved, it had to find a new workforce.

Meat processing facilities in rural areas generally do not have to compete with other factories for workers, and often recruit workers from out of the area, especially to staff second or night shifts. Refugee resettlement in the 1970s and 1980s brought Asians to the Midwest, and the 1986 IRCA facilitated the geographical and occupational mobility of newly legalized Mexicans. Many saw moving from seasonal farm to year-round meat processing jobs as a step up the US job ladder.

There is little systematic data on employer preferences for particular types of workers. Poultry plant managers in the late 1980s told interviewers that Asians and Hispanics had a 'better work ethic' than local Blacks and Whites. Griffith also noted that economic growth offered local workers other job opportunities, encouraging many to quit meatpacking jobs. Many immigrant workers moved to meatpacking jobs on their own, but some plants offered cash bonuses of several hundred dollars to current workers and others who referred persons who stayed on the job 60 or 90 days. Networks evolved to bring US-born as well as Mexican-born Hispanic workers from South Texas and other areas with high unemployment rates to midwestern meatpacking plants.

Once a core group of Asians or Hispanics is employed in a plant, network hiring can take over recruitment, with current workers bringing friends and relatives to fill vacant jobs (Griffith, 1988, p. 35). Network hiring shifts most recruitment and training costs to currently employed workers, who bring only those who can do the work and often act as the mentors of newly hired workers. The Los Angeles Times on 10–12 November 1996 profiled one network that moved workers along the so-called 'chicken trail' from South Texas to Missouri (Katz, 1996). Hudson Foods, based just outside Noel, Missouri, paid South Texas recruiter B. Chapman US$175 for each worker who was referred and hired in its chicken processing plant. The reporter was selected by Chapman, traveled to Noel, and lived with 135 other migrant poultry workers in a converted motel, paying US$45 per week in rent.

Hudson employed 200 workers to process 1.3 million chickens a week. Worker turnover was very high; Hudson reportedly hired 50 new workers a month. Approximately 45% of the unionized labor force was Latino, and Hudson offered the current employees who referred the new workers a bonus of US$300. Hudson's Human Resources Director said: "there's a large number of jobs that very few citizens in the US want to do, but they're there and they need to be done...One of the social goods the poultry industry provides is employing people who would otherwise have a great deal of trouble getting employed."

The arrival of immigrant workers at Hudson and other meat processing plants rarely displaces local workers and sometimes increases productivity. New plants in rural areas tend to have more labor-saving and worker-friendly technologies, providing a cleaner and safer work environment than was available to workers in older urban plants. If the availability of immigrant workers allows a second work shift, employers may invest in more expensive air- and electric-powered knives that make work easier for all workers, potentially reducing the injuries and illnesses in meatpacking.

Enforcement

Meatpacking drew the attention of immigration enforcement agencies during the late 1990s, when an estimated 25% of meatpacking workers were unauthorized. Operation Vanguard subpoenaed employment records from meatpacking plants, compared information provided by newly hired workers on I-9 forms with government databases, and instructed employers to ask employees who appeared to be unauthorized to clear up discrepancies in their records before INS agents came to the plant to interview them. When employees were informed of INS suspicions that they were unauthorized, most of the workers quit.

Vanguard was attacked by meatpackers, farmers, unions, and Hispanic groups, prompting INS headquarters to order its suspension in 2000. The subsequent lack of enforcement contributed to the jump in the Hispanic share of employment in meatpacking between 2000 and 2005. However, beginning in 2006, meatpacking plants were often targeted in raids seeking unauthorized workers. The Immigration and Customs Enforcement agency used 1000 agents to inspect workers at six plants owned by Swift on 12 December 2006, arresting almost 1300 of the 7000 workers employed on the day shift in these plants. Crider Inc., a poultry processor in Stillmore, Georgia, lost three-fourths of its 900-strong workforce when ICE agents mounted a raid on Labor Day weekend in 2006. In the aftermath of the raids, many meatpackers enrolled in E-Verify, the Internet-based database that allows employers to check the legal status of newly hired workers.

The result was a reversal of the growing share of Hispanics in meatpacking between 2005 and 2010. EEOC data, which report the sex, race, and ethnicity of employees (www.eeoc.gov/eeoc/statistics/employment/jobpat-eeo1/index.cfm) in most US establishments, show that the share of Hispanic workers in food manufacturing and meat packing rose rapidly between 2000 and 2005 but fell between 2005 and 2010. In 2000, Hispanics were 38% of all employees in animal slaughtering and 48% of animal slaughtering laborers. The Hispanic share of animal slaughtering workers rose by approximately 10%

points between 2000 and 2005, and then fell to 2000 levels or below by 2010.

Reasons for the rising share of Hispanics among laborers in meatpacking include network hiring and recruitment during periods of low unemployment. Reasons for the falling share of Hispanics since 2005 include well publicized workplace raids in 2006–07 and I-9 audits since the 2008–09 recession that increased unemployment and made year-round meatpacking jobs that often pay US$12 an hour more attractive, and more employers enrolling in E-Verify, which may discourage unauthorized workers from applying for jobs.

Community Impacts

The arrival of Hispanic workers can quickly change the face of rural areas that sometimes have not experienced significant immigration for a century. The new residents have been welcomed in most areas, especially those losing people and jobs. Hispanic immigrant meatpacking workers buy and rent homes and shop at local stores, helping to stabilize local economies.

There are also new tensions with demographic change. Many local residents complain about the side effects of the changing labor force, including more students with limited English proficiency in local schools and more uninsured patients seeking health care at local clinics and emergency rooms. Many meat processing plants provide health insurance and other benefits after 60 or 120 days of employment but, with high turnover, a significant share of the workers in a particular plant may not have employer-provided health insurance.

Two extremes mark the reactions of meat processors to these externalities from hiring migrant workers. Some recognize that they are hiring workers from outside the area with little English and formal schooling, and some have formed partnerships with local community colleges and high schools to offer classes in English, finance, and other life skills to their workers. For example, Tyson Foods has an education assistance plan that reimburses 75% of the cost of tuition, books, and fees (up to US$3500 a year) for coursework that helps to meet the company's business needs. In Grand Island, Nebraska, Swift & Co. built a two-classroom school near its plant in 2002 so that workers could attend high school classes before and after their work shifts; the local school district provided a teacher and a teacher's aide.

The other end of the spectrum is marked by processors who say that their major economic contribution is the facility they provide for local farmers and the payroll they provide to local workers. Meatpackers who do not make impact payments, sponsor sports events, and inform community leaders of their plans may contribute to the backlash against immigration in some communities. Some cities and counties have voted against zoning or other changes needed to open or reopen meat processing facilities.

Many rural counties in the Midwest are losing people, forcing residents to choose between depopulation and diversity. Over the past 50 years, census-defined rural counties without a city of at least 2500 people lost more than a third of residents in 11 Great Plains states, with farm-based counties away from interstate highways losing the most residents. Of the 99 US counties with the highest percentage of residents older than 85 years, all but two are in the Great Plains.

The General Accounting Office (1998) concluded that there were mixed effects of immigrants. On the one hand, the arrival of immigrants helped to stabilize populations that were shrinking, and counties with meatpacking plants had faster increases in per capita income and retail sales than non-meatpacking countries. On the other hand, the increased number of poor and limited-English proficient children in schools and very high turnover among workers prompted teachers to complain that it was very hard to educate children who may be in their classrooms for only a short period. The housing market tightened with the influx of workers, especially for inexpensive rental housing such as mobile homes.

Conclusions

Farm operators, unpaid family workers, and hired workers are the three major types of workers employed on US farms. Over the past quarter century, the share of average employment contributed by hired workers has been rising, so that hired workers are now about 60% of average employment on US farms. These hired workers are concentrated in three interrelated ways, by commodity, size of farm, and geography, so that most hired workers are employed on large farms in California and a few other states that produce labor-intensive fruit and vegetable commodities. Dairies and nurseries are also important employers of farm workers.

Over half of the hired workers on US farms have been unauthorized since the mid-1990s, and almost all new entrants to the farm workforce are unauthorized. Farm work is more often a less-than-10-year job than a career, and older hired workers who find nonfarm jobs are typically replaced by youthful newcomers from rural Mexico, giving especially seasonal agriculture something of a revolving-door labor market.

This revolving door is threatened by immigration reforms that may make it more difficult for newcomers to enter from abroad. Farm employers want new and modified guest worker programs to make it easier to hire the foreign workers who are over two-thirds of US farm workers, whereas worker advocates argue that there must be strong recruitment, housing, and wage requirements to protect foreign and US workers. Farm employers and worker advocates reached a compromise in 2000 known as AgJOBS to legalize currently unauthorized farm workers and make it easier for farm employers to hire guest workers in the future, but they have been unable to persuade Congress to enact AgJOBS.

Instead, the federal government has gradually tightened border and interior enforcement, and some states have implemented immigration control laws, in ways that have generated farm labor shortage complaints. Most complaints of labor shortage reflect special circumstances, such as particularly light or late harvests in remote areas that do not attract workers, but farmers fear that they could face labor shortages that would result in sharply higher wages. For this reason, farm employers have a keen interest in immigration reform proposals.

Given immigration policy uncertainties, many farmers are hedging their bets. Most oppose federal laws requiring employers to use E-Verify to check new hires and the enactment

of state laws penalizing employers and unauthorized workers unless these enforcement efforts are accompanied by employer-friendly guest worker program. Some employers are investing in housing so that they can employ H-2A guest workers, and some are investing in mechanical aids to enlarge the pool of available workers and labor-saving mechanization to adjust to fewer and more expensive workers. History is unlikely to repeat itself and flood the farm labor market with new workers, as in the late 1980s, but it is not clear whether and how fas farm labor costs under *status quo* and immigration reform scenarios will change.

Glossary

Ad valorem taxation A tax based on the fair market value of the real estate. The value is calculated on the property's potential for its highest and best use.

Appropriation doctrine State legislative delineation of rights and priorities to water resources.

Conservation easement An easement that sets forth conservation objectives such as preserving wildlife habitats, riparian lands, forests, or farmland.

Point-source pollution Water pollution from a single point such as a pipe or concentrated animal feeding operation.

Preferential assessment The modification of ad valorem taxation under which qualifying land is assessed according to its current use value rather than fair market value.

Production contract Agreement by which a producer agrees to feed and care for livestock or poultry owned by a contractor for payment.

Right-to-farm law Legislative antinuisance provisions which say qualifying activities are not nuisances so that farmers have the right to continue farming even though their activities are objectionable to neighbors.

Riparian doctrine Common law doctrine delineating rights to water resources.

Security agreement A contractual arrangement in which the borrower assigns collateral as security for the repayment of a debt to the lender.

Transferable development rights A form of development control under which landowners are provided financial incentives to conserve agricultural land uses.

Introduction

The hard economic times of the 1930s contributed to ideas that farmers and farm communities needed legal expertise. In 1933, V. O. Braun, a lawyer from Owosso, Michigan, published a book titled, *Agricultural and Business Law for the Farmer*. Twenty years later, faculty from land grant universities in the north-central region recognized the changing structure of agriculture and published proceedings from a seminar titled, 'Legal Aspects of the Family Farm Corporation.' The communications and ideas of this faculty led to discussions of having more structured venues for communicating information dealing with agricultural law.

Meanwhile, other legal experts developed materials and published information on agricultural law. In 1979, the *Agricultural Law Journal* (discontinued) was initiated to provide scholarly articles about agricultural legal issues. Articles in law reviews and other publications provided a foundation for agricultural law in the 1980s. A multivolume treatise, *Harl, Agricultural Law*, provided in-depth coverage of agricultural law topics. The authors and their literature shaped the issues, legislation, and jurisprudence forming agricultural law.

Agricultural law includes numerous legal topics and agricultural law practices have changed over the years. The early issues centered on property and business arrangements. In the 1970s, many agricultural lawyers spent considerable amounts of time on property taxation and estate planning. Farm financial issues in the 1980s drew attention to financial matters including bankruptcy. The industrialization of agriculture and concerns about environmental quality in the 1990s meant that agricultural law expanded to encompass issues such as water pollution from concentrated animal feeding operations (CAFOs). Issues on genetically modified organisms, animal welfare, agricultural labor, and food safety have also become important. The potential breadth of an agricultural attorney is unlimited. Agricultural law can be described as the application of legal principles to agricultural, rural, environmental, business, and food issues.

A discussion of the topics of agricultural law would not be complete without a foundation of the institutions that have been developed to support agricultural lawyers. Although any law school graduate may become an agricultural lawyer, specialized agricultural law organizations and publications have become prominent in assisting lawyers in serving agricultural clients. These clients include farmers and ranchers producing food and fiber products, input suppliers, processing facilities, retailers, distributers, and customers and consumers of agricultural products. Thus, the discussion of agricultural law is very broad and no single term includes the entire clientele. For simplicity, the clientele will be referred to as 'producers' despite the fact that it includes marketers and others.

For a summary of agricultural law topics, the article will look at the US and what agricultural law means to agricultural producers and their counsel. Part II describes some of the resources that are available to persons wanting more information about agricultural law. The discussion of topics commences in Part III with transactions in real property. Part IV covers leases and granting access to property, whereas Part V looks at agricultural nuisances. Part VI addresses business arrangements, whereas Part VII looks at governmental regulations and programs that provide rules that are important in maintaining a viable agricultural sector. Governmental regulations dealing with water resources and environmental quality are examined in Parts VIII and IX. Finally, a collection of other agricultural law topics is covered in Part X.

Institutions Supporting Agricultural Law

At the suggestion of the Farm Foundation, a group of American lawyers dealing with agriculture converged in 1980 and

established the American Agricultural Law Association (AALA), a national organization of professionals with interests in agricultural law. This organization is a nonprofit organization that serves as the preeminent organization for agricultural law in the US. Membership consists of a broad range of agricultural law practitioners, academics, government workers, and lawyers working for agricultural interest groups (Uchtmann, 2007). The AALA has yearly annual continuing legal education conferences that address a multitude of agricultural law topics. The AALA also has a LISTSERV so that members can make inquiries and share information.

In Europe, national agricultural law associations exist in many countries. In 1957, lawyers founded the Comité Européen de Droit Rural (CEDR), also referred to as the European Council for Agricultural Law. The CEDR is the only pan-European organization representing lawyers and professionals interested in rural law and has consultative status with the Council of Europe. The CEDR holds a European Congress on Rural Law in odd-numbered years and invites representatives from the AALA and other countries to participate.

Several American law schools offer agricultural law courses in which students learn subject matter that is important for rural law practices. In 1981, the University of Arkansas launched an advanced master of law degree in Agricultural Law, which has evolved into the LL.M. in agricultural and food law. Students with a law degree return to law school for more specialized training. This program remains the only American advanced degree in agricultural law and attracts students from all over the world. Law schools at Drake University, Penn State University, and in Canada, the University of Saskatchewan, have centers specializing in agricultural law that organize programs and publish information to assist others with agricultural law issues.

Several American land grant universities offer undergraduate courses in agricultural law and related legal subjects, and a few have agricultural law centers. Undergraduate students receive training in law topics that will help them in their careers and many secure jobs with agricultural business firms. Courses may include agricultural law, agribusiness law, environmental law, tax law, and food law. Some universities have minors in agricultural or agribusiness law.

Nearly 20 universities have joined an interactive distance education alliance of universities headquartered at Kansas State University known as Great Plains IDEA. In 2012, AG*IDEA, an affiliate of Great Plains IDEA, offered the first undergraduate agricultural and environmental law courses through distance learning technology. Students are able to complete a minor in agricultural or environmental law through the AG*IDEA program.

Land grant universities may also have an agricultural law expert who provides training sessions and assistance through the Cooperative Extension Service. This faculty develop and deliver programs in their state to assist agricultural producers and others by providing information concerning legal issues. The programs by extension faculty involve educational training rather than giving legal advice.

Other specialized groups provide training, support, and services for persons needing legal assistance in rural communities. The American Bar Association (ABA) has various subcommittees that address agricultural law. Many state bar associations have agricultural law committees that assist rural practitioners through contacts and programs.

The National Agricultural Law Center at the University of Arkansas is an agricultural law research and information facility that is independent and national in scope. In conjunction with the AALA, it maintains an agricultural law blog (http://www.agandfoodlaw.com/2009/01/about-this-blog.html) as a resource for securing information on many agricultural law topics. The Farmers' Legal Action Group, Inc. of St. Paul, Minnesota, offers legal services to family farmers and their rural communities to help keep family farmers on the land.

Specialized literature on agricultural law is also prominent and assists practicing attorneys in becoming aware of contemporary legal developments that may impact their clients. Four American law schools have law journals specifically dealing with agricultural and food law. The oldest is Drake University's *Drake Journal of Agricultural Law*. The University of Arkansas Law School publishes the *Journal of Food Law and Policy*, the University of Kentucky the *Kentucky Journal of Equine, Agriculture, and Natural Resources Law*, and the San Joaquin Law School the *San Joaquin Agricultural Law Review*. Other journals on agricultural law include the *Jahrbuch des Agrarrechts* (University of Göttingen, Germany), *Agrarisch Recht* (Institute for Agricultural Law, Wageningen, The Netherlands), and the *European Food and Feed Law Review* (Lexxion Verlagsgesellschaft mbH, Berlin).

Transactions in Real Property

One of the most conspicuous subject areas of agricultural law deals with real property. Deeds, ad valorem taxation, preferential agricultural assessment, farmland preservation, and corporate farm laws are issues that have been important components of the practices of agricultural lawyers.

Real property is often an agricultural producer's major asset and agricultural lawyers assist in the preparation of documents used with the purchase and sale of real estate. Documents may include deeds, lien releases, easements, mortgages, loans, and guarantees of title. Counselors also assist clients by checking for liens and encumbrances against the property. Other advice may address alternatives regarding the ownership of property, as a producer may want to use a business entity such as a partnership, limited liability company, or corporation.

Because producers use vast acreages for the production of crops and animals, ad valorem taxation on real estate is an important issue. Under ad valorem taxation, land is assessed at fair market value. Whenever nearby properties are used for nonagricultural purposes with higher market values, assessors can base the farmland's value on its potential to be developed for nonagricultural purposes. This means that farmland next to residential and commercial properties can have higher property taxes than comparable agricultural land in the more distant countryside.

In the 1950s, subdivisions and nonagricultural land uses were moving into agricultural areas near populated areas causing the property taxes of agricultural landowners to increase to an extent that taxes became a financial impediment to viable production. To assist in preserving farmland, farm groups and agricultural lawyers advanced a new taxation model

known as preferential assessment. Preferential assessment involves the assessment of qualifying land at its use value rather than fair market value. Generally, the adoption of preferential assessment requires an amendment to the state constitution and the adoption of legislation delineating use value qualifications. Under preferential assessment, landowners may be required to sign contractual agreements to keep their lands in agricultural production for a number of years. Legal counselors provide property owners advice about the advantages and potential problems of entering such agreements.

Agricultural lawyers are also involved with efforts to preserve farmland. They work with landowner clients to determine whether to participate in state programs involving preferential assessment, farmland preservation, conservation easements, and transferrable development rights. Agricultural lawyers may also be involved in helping communities develop zoning ordinances and agricultural districts that are supportive of continued agricultural production.

In cases where owners want to protect agricultural land, legal counsel may draft a conservation easement to preclude the future development of the property. A conservation easement sets forth conservation objectives to preserve wildlife habitats, riparian lands, forests, or farmland. An easement may delineate purposes for which the property may not be used and its restrictions are perpetual. Under the applicable state law, an organization holds the conservation easement and is granted the power to constrain the rights of the landowner.

By voluntarily placing a conservation easement on property to preserve farmland, landowners qualify for tax benefits. Because the property cannot be developed, its real estate taxes may be lower than comparable properties without an easement. The value of a donation of a conservation easement is deductible from the donor's income under federal income tax law. The value of property subject to a conservation easement may also be taken into account for estate tax purposes.

Another institution used to preserve farmland involves a state or local program for transferable development rights (TDRs). Under a TDR program, a rural landowner sells development rights to private developers and the farmland is limited in its future uses. By purchasing development rights, developers are granted rights to develop properties at higher densities in nonrural areas. Under this arrangement, agricultural producers receive compensation without having to sell or develop their lands.

Legal counselors may be called on to assist clients in forming farm corporations that comply with their state's legislation against corporate farms. Several states in the upper Midwest have delineated prohibitions on the corporate ownership of farmland with exceptions for family farms and active agricultural producers. Justifications for limiting corporations from owning farmland include a dislike for industrialized agribusiness and absentee ownership as well as concerns about environmental damages and rural depopulation.

Leases of Real Estate Interests and Granting Access to Property

Because farmland is expensive and heirs are often hesitant to sell family farm properties, many producers rent considerable acreage for agricultural production. Lawyers are needed to help with contractual provisions that set forth agreed terms between landlords and tenants. With new emphasis on domestic energy sources, producers are entering leases to allow others to develop wind energy resources or engage in oil, gas, and mineral extraction. Rural property owners also may require legal assistance for arrangements involving others coming onto their properties for recreational, hunting, and agritourism purposes.

Two types of traditional farm leases covering the rental of land to grow crops are used: crop share leases and cash rent leases. Crop share leases generally involve a division of supplying farm inputs and sharing the value of the harvested crop. These arrangements facilitate the extension of credit by the landlord and sharing the risks of a poor crop between the landlord and tenant. Although the landlord supplies the land, typically the tenant pays for the variable inputs including fertilizer, seed, pesticides, irrigation, and cultivation.

Cash rent leases entail the landlord receiving a cash payment in exchange for the tenant's use of the land. Under cash rent leases, landlords do not share with expenses or income from the production of the crop. This means the tenant assumes all of the risks of crop production. Tenants often seek multiyear leases so that they can apply fertilizer nutrients to enhance production and receive the benefits of nutrients that remain in the soil for a subsequent year's crop. Leases also may need to address credit arrangements, liens on the crop, options to purchase, and insolvency.

Many rural landowners have opportunities to consider leasing their properties for activities including hunting, recreation, wind energy, and oil, gas, and mineral extraction. Before entering these leases, landowners need to consider a range of potential consequences that may accompany giving others access to their properties. One major issue is whether the property owner might be held liable for an accident to another person who is on the leased property. Because an accident might result in large medical expenses and personal injury costs, provisions might assign responsibilities or require insurance coverage.

Landowners entering leases for the extraction of oil and gas need to be concerned about environmental damages. A majority of these leases are written by the drilling companies and fail to adequately address responsibilities regarding land contamination and degradation. Without legal advice, landowners may sign leases that fail to hold drilling companies responsible for damages associated with faulty equipment and negligent activities. Roads and pads for drilling activities may adversely affect existing property uses. Hazardous fracturing chemicals may be released from leaking casings, blowouts, spills, and flowback that contaminate the land, surface water, or even groundwater. After a well is drilled, the drilling company may leave sump holes, mud pits, and obsolete equipment on the site, and contaminants on the property may mean it has diminished in value. These potential problems suggest that competent legal advice should be secured before signing a lease.

Over the past half century, farm interest groups have advanced several legislative ideas to limit liability for accidents by persons invited on rural properties. State recreational use statutes were adopted to provide incentives for property owners to allow others to use their property gratuitously by

altering the duties property owners owe recreational users. By redefining the duty of care, a state's recreational use statute makes it less likely that a property owner will be liable for damages to an injured recreational user. Counsel can help property owners determine whether they qualify under a statute for protection against liability.

Complex equine liability statutes have been enacted by more than 40 states to help protect owners and others from liability for equestrian accidents. Most equine liability statutes declare that equine owners and others are not liable for injuries resulting from the inherent risks of equine activities. In addition, equine liability statutes may specify duties of care for providers and have requirements for warning signs and liability releases. Legal counsel can help property owners meet conditions necessary to qualify for protection against liability for some accidents.

Agricultural lawyers also assist clients who want to provide activities for tourists. Agritourism has become an important source of income for some producers, with activities including petting zoos, hay rides, corn mazes, pick-your-own operations, theme parties, picnics, and winery tours. However, producers need to be concerned about financial liability for persons injured on their properties, and several states have adopted agritourism statutes to limit liability. The most common legislative term says that participants should assume inherent risks while participating in agritourism activities.

Agricultural Nuisances

With the expansion of residential areas into the countryside in the 1950s, conflicts between agricultural practices and nonfarm residential property users became a problem. Persons living in suburbia did not like the noises, dust, and smells that accompany aspects of agricultural production. Many of the objections centered on practices involving animal manure. Agricultural lawyers were called on to defend producers against lawsuits based on nuisance. If a jury found that an agricultural practice was a nuisance, the producer could be enjoined from continuing the practice. This resulted in producers not being able to profitably continue with their farming operations. Moreover, producers were hesitant to make investments in their operations because of uncertainties about future complaints from neighbors.

To counter injunctive relief available in nuisance lawsuits, state legislatures adopted antinuisance laws. These laws became known as 'right-to-farm' laws because by precluding injunctive relief under nuisance law, they enable producers to continue farming despite the objectionable activities. A majority of the right-to-farm laws adopted a 'coming-to-the-nuisance' exception under which a person who moved next to an established farm could not claim the farm's activities were a nuisance. In this manner, right-to-farm laws enabled producers to continue with activities despite the fact that the neighbors felt the activities were a nuisance. Right-to-farm laws in some states also offer antinuisance protection to qualifying agricultural businesses.

Because right-to-farm laws delineate a state's antinuisance rules, they preempt attempts by local governments to regulate agricultural nuisances. However, local governments may continue to regulate agricultural activities under zoning or local health laws unless state legislation says otherwise. Although right-to-farm laws operate to protect producers against some nuisance lawsuits, legal counsel may be required to evaluate whether the law applies to the facts of a given situation. Each state's right-to-farm law contains specialized provisions delineating qualifications before the protection applies. Moreover, amendments to state right-to-farm laws have resulted in very different provisions for each state.

Another issue under right-to-farm laws is whether the provisions of a state law constitute an unconstitutional taking. In 1998, an Iowa right-to-farm law was found to create an easement that constituted an unconstitutional taking of private property (Centner, 2000). The court felt that the Iowa legislature went too far in attempting to preserve farmland, and in a subsequent lawsuit, this was related to the protection of property rights provided by the Iowa Constitution. Safeguards and regulatory provisions incorporated in right-to-farm laws of other states should thwart similar constitutional challenges.

Business Arrangements

Another prominent area of agricultural law deals with business arrangements used by producers and related firms in the production and marketing of agricultural products. Legal counselors give advice on contractual agreements, help clients form business entities, oversee documents used in securing financing, assist indebted operators with bankruptcy, and provide advice on estate planning.

Producers generally seek assistance from legal counsel whenever entering a major contractual obligation to ascertain that the agreement accomplishes its intended purpose without creating any unnecessary complications. Important contracts include agreements for forming businesses, purchasing businesses, buying and selling property, mortgages, leases, loans, easements, lien releases, and security agreements that pledge collateral as security for borrowing money. Counsel can explain the meaning of legal terms, add provisions to offer protection against potential problems, suggest the removal of onerous or unnecessary provisions, and offer advice on alternatives.

Agricultural producers raising large numbers of animals, especially hogs and poultry, often sign production or marketing contracts with business firms known as integrators. The contracts are written by the integrators with detailed provisions affecting production activities. Under a production contract, the producer feeds and cares for the animals and is paid pursuant to a contractual pricing formula determined by the performance of the animals. Under a marketing contract, the producer agrees to sell or deliver animals to an integrator according to pricing terms set in the contract. Agricultural lawyers may be needed to offer advice on the terms of these contracts, although producers may have few options for alternative marketing outlets for their animals (Looney and Poole, 1999).

Agricultural law practitioners help clients make decisions about whether to operate as a sole proprietorship or to form a

business entity. Producers may find it advantageous to form a business entity to raise funds, have family members or friends as partial owners, limit liability for losses and accidents, and transfer assets on death. Each state has separate legislation governing business entities that include corporations, Subchapter S corporations, cooperatives, partnerships, limited partnerships, and limited liability companies.

A disadvantage of some business entities is income taxation at the firm level. Legal counsel can explain how each business entity might fit the needs of a client's farming situation. Favorable state legislation regarding limited liability companies suggests that this form of business is well suited for many small businesses. A limited liability company allows income to pass through to owners so that there is only a single level of income tax and liability is limited to the assets of the company.

A major reason for forming a business entity is liability for accidents. Farming is a dangerous occupation given the chemicals and equipment used in producing food and animals. Any farm or business that employs nonfamily workers or has people coming onto the property should be concerned about being held liable for damages from an accident. For example, a worker may suffer severe injuries from operating a piece of farm equipment. This suggests that the operator may want to consider forming some type of business entity that would own the land and equipment and employ the worker. The producer could own other assets outside the business entity, such as a house, bank accounts, stocks, and bonds. By structuring the business entity as owner of machinery and property and the employer of workers, a producer may successfully shield assets outside the entity from liability related to a major accident.

Over the years, agricultural lawyers have been involved with helping producers form agricultural cooperatives, and assisting clients in their dealings with their cooperatives. Distinct legal provisions for this form of business and controversies on paying out dividends to members have meant that specialized legal counselors are needed to assist producers as well as cooperatives.

Counselors help agricultural producers and agribusiness firms grapple with problems connected with credit and security interests (Meyer, 2010). Producers often seek counsel to assist with documents involved in securing financing for the purchase of seeds, fertilizer, equipment, and other production inputs. Agricultural producers depend on the advice of agricultural lawyers before signing these contractual arrangements to ascertain that terms are reasonable and do not delineate any adverse provision that may interfere with future business arrangements.

When borrowing money to purchase personal property, borrowers sign a security agreement listing collateral as security for the repayment of the loan. Security agreements have significant ramifications concerning ownership and rights in property. Legal advice is important when delineating terms of a security agreement because of the options available for listing collateral. Collateral may include accounts, goods, stock, livestock, equipment, inventory, and farm products. Special rules apply to farm products as opposed to other types of collateral so different financial arrangements may be needed to safeguard the interests of a client.

Lenders often want to list several categories of collateral to guarantee assets for the repayment of debts. Borrowers want to limit the collateral listed in a security agreement so that they have unencumbered collateral to use in securing additional financing. Counselors can advise clients on which collateral to list and advise them on their rights in collateral listed in more than one security agreement. Because multiple parties may have a security interest in the same property, a major objective is to help clients structure business transactions so that no money is lost because of the insolvency of another. Lawyers also advise clients on how they might secure priority on collateral in the possession of someone else.

Owing to the cyclical nature of commodity prices and other problems, agricultural producers may become so indebted that they need to consider bankruptcy. Poor economic decisions in the 1970s led many producers to experience financial difficulties and secure the assistance of agricultural lawyers for advice about bankruptcy. Competent legal counsel is important because bankruptcy does not need to result in the liquidation of property. Rather, separate chapters of the federal Bankruptcy Code offer different bankruptcy options for financially distressed producers.

In 1986, Article 12 of the federal Bankruptcy Code was adopted to provide advantageous provisions for qualifying financially challenged family farmers (Geyer, 1997). The article allows farmers to demand concessions from secured creditors and write down secured debt. Under the article's provisions, farmers can be rehabilitated and continue with their farming operations. Legal counselors help farmers use bankruptcy provisions to reorganize their businesses with less debt and continue farming.

The imposition of federal gift and estate taxes means that estate planning is an important part of many agricultural law practices. Owing to the value of farm buildings, equipment, and farmland, agricultural producers often have sizable estates. With the death of a farm owner, the payment of estate taxes may interfere with the transfer of a farm to heirs. Because federal estate tax provisions change, legal counselors help clients structure estate plans to minimize taxes while achieving the transfer of assets to desired beneficiaries. For example, a producer may want to structure assets to take advantage of the special use valuation of farmland for estate taxation purposes under Section 2032 A of the Internal Revenue Code. Because a decedent must meet requirements concerning the ownership of qualified real and personal property, as well as the use of the property for 10 years after death, planning is needed to qualify for this valuation provision.

Governmental Regulations and Programs

The uniqueness of agriculture has led legislative bodies to adopt special programs and exceptions that are important to the profitability of many producers. Agricultural lawyers are called on to assist producers in structuring their businesses to take advantage of benefits provided by federal farm programs and to comply with applicable regulations. Legislative and regulatory provisions dealing with income taxation, federal farm programs, disaster and insurance programs, marketing

issues, and product labeling are important to many farm businesses.

Federal income taxation continues to be a major issue for many agricultural producers because of changes to the Internal Revenue Code. Legal counselors provide suggestions for structuring business activities to take advantage of deductions and credits to reduce federal and state income taxes. Many state Cooperative Extension Services offer yearly income tax training for legal practitioners and accountants that provides updates on tax provisions and ideas for assisting clients in reducing taxable income.

Agricultural producers have a variety of property that may qualify for income tax deductions, credits, and favorable depreciation schedules. Tax law provisions on capital gains rates, domestic production activities deductions, depreciation, weather-related event taxation, like-kind exchanges, government payments, income averaging, and self-employment taxes have meant that legal counsel specializing in tax law can offer suggestions to help producers reduce income tax bills. In some situations, counsel may advise producers to generate expenses such as investing in new equipment to provide offsets and deductions to lower tax bills. Other advice may involve like-kind exchanges that avoid recognizing gains from the sale of equipment and requesting selected types of payments from governmental farm programs to defer income.

Owing to the pervasive regulation of agricultural activities by the federal government, many agricultural lawyers have developed expertise in administrative issues accompanying agency decisions. This requires familiarity with federal administrative law, the rights of producers under a given governmental program, and dealing with the agency when there is an issue about qualifying for a program or program benefits. Issues between agricultural producers and the government under federal farm programs have provided agricultural attorneys opportunities to help producers secure earned benefits.

Over the years, financial incentives offered through federal farm programs have been important to producers. Historic federal farm programs have provided price supports, income supports, recourse loans, marketing orders, and various assistance programs to support continued agricultural production. As new programs are introduced, legal counselors can assist agricultural producers in determining ramifications of participation. Other advice may center on maintaining flexibility for adjusting to potential changes in federal programs and helping producers restructure so they can participate.

Agricultural lawyers are also needed when a disaster strikes and a producer seeks advice on how to qualify for assistance. Under the Federal Crop Insurance Act, agricultural producers can secure insurance to manage risk and have protection against substantial losses that occur because of drought, flood, or other national disasters. Legal counsel may be sought by a producer with a crop insurance or disaster claim that was disallowed for failure to follow 'good farming practices.' Counsel can help secure an expert's opinion to develop a record that supports qualification for a claim. The overturning of a decision by an insurer or governmental agency requires considerable proof and needs to be handled correctly to succeed.

Other federal disaster assistance programs are also important to agricultural producers who experience a major natural disaster. Lawyers can assist clients in determining whether they qualify for payments under the Emergency Loan Program, Disaster Set-Aside Program, Noninsured Crop Disaster Assistance Program, Supplemental Revenue Assistance Payments, Tree Assistance Program, Livestock Forage Disaster Program, Haying and Grazing of the Conservation Reserve Program, Conservation Stewardship Program, Livestock Indemnity Program, and the Emergency Conservation Program.

Because producers of livestock often confront a market with few buyers for their animals, Congress enacted the Packers and Stockyards Act. The act was intended to help producers by preventing processors from creating monopolies. Given the market concentration of major firms as well as the contractual arrangements of many processors, individual producers may have little choice in marketing outlets. Counsel can help producers determine whether a processor's practices have an adverse effect on competition contrary to the provisions of the Packers and Stockyards Act.

Producers and buyers of fruits and vegetables have special needs accompanying marketing transactions for fresh produce. Provisions of the federal Perishable Agricultural Commodities Act govern various aspects of the marketing arrangements to give assurance that growers are paid. Under the act, a trust is formed for receivables and proceeds from the sale of produce. Agricultural lawyers work with growers and dealers to meet the financial obligations covered by federal law.

Consumer demand for specialized food products and more information on food labels has created opportunities for differentiating products to garner higher prices. Food product marketers depend on product labels to position their products in the marketplace. Yet the labels must conform to labeling requirements set forth by federal and state laws. If information on a label is false or misleading, it is misbranded. Moreover, the absence of information relevant to the issue may cause labeling to be misleading. Legal counsel may be needed to ascertain that a client's labeling information complies with misbranding legislation. Other advice might be needed to determine the legality of voluntary labeling involving negative characteristics such as rBST and genetically modified organisms.

The US Department of Agriculture (USDA) regulates labels on some food products. Its organic seal may be used on products that were grown or produced in compliance with National Organic Program regulations. Under the USDA's organic program, detailed requirements on production practices must be followed before a product can be labeled as 'organic.' Certifying agents accredited by USDA are used to provide third-party certification of producers' organic plans. Organic food production has become an important segment of agricultural production.

Legal counsel remains important in organic production because of unresolved issues and controversies about qualifications. Producers continue to need assistance in comprehending the rules overseeing organic certification. Legal counsel may be necessary to seek redress for spray drift damages from neighboring property owners. Organic labels containing value judgments may be found to be misleading under the Food, Drug, and Cosmetic Act. Insufficient testing and minimal oversight of certifiers may lead to controversies about products labeled as organic. Legal counsel may be needed to represent producers or consumers in these disputes.

The USDA also oversees country-of-origin labeling and labels containing process information such as notations on irradiation and antibiotics. Given the complexities of misbranding law, legal counsel will undoubtedly be asked to examine a proposed label with such information to ascertain compliance with the law. Legal advice may also be needed on conforming to packaging requirements established by the Federal Trade Commission.

Related to food labeling are new legal requirements for menu-labeling at restaurants adopted by the Food and Drug Administration. The Patient Protection and Affordable Care Act of 2010 was enacted by Congress to govern restaurant menu-labeling. Under the law, caloric information to help people control obesity must be provided by restaurants, similar retail food establishments, and vending machine operators that are part of a chain with 20 or more locations or 20 or more vending machines. The act also preempts local and state regulations, and allows restaurant and vending machine operators to voluntarily elect to be subject to the federal regulations and thereby avoid having to comply with state and local regulations. Legal counsel can provide advice on voluntary and required information on labeling to help clients maintain compliance with the applicable regulations.

Water Resources

The production of food and fiber products is dependent on the availability of water resources. Both water quantity and quality affect the viability of crop and animal production. In more and more situations, agricultural producers need legal advice on how to comply with legal requirements dealing with water resources. Additional legal advice may examine the future availability of sufficient water and how to address issues of water quality.

Owing to the provisions of the US Constitution, the federal government is involved in water issues that affect agricultural producers. Provisions regarding treaties with Indian tribes, compacts between and among states, and the Commerce Clause have justified Congressional action in enacting regulations governing water allocations, flood control, irrigation projects, and pollution. Simultaneously, each state has its own water law. Legal counsel may be called on to assist producers in determining rights to water and the legality of using water from a water body.

State water law may incorporate principles of the riparian doctrine, delineate an appropriation doctrine governing water rights, or use a combination of both. The riparian doctrine was adopted by most states in the eastern part of the US. Water usage is part of land ownership and applies to landowners adjacent to surface waters. There is a division between natural use and artificial uses of water. A landowner may use unlimited quantities of water for natural uses but only reasonable quantities for artificial water uses such as impoundments and irrigation.

Conflicts involving insufficient quantities of water in states following the riparian doctrine have led state legislatures to adopt water-permitting systems. This means that water usage for irrigating crops is governed by the riparian doctrine amended by state appropriation provisions. Counsel may be needed to advise agricultural producers on their rights under the permitting system and how to qualify for future rights to water resources.

In situations of water scarcity, the riparian doctrine does not provide a reasonable reconciliation of competing uses for water resources. This has led state legislatures in the western part of the US to adopt appropriation doctrines to delineate their state's rules for water usage. Each state has adopted rules delineating priority rights in the use of water resources. The first person to use and file for the use of water from a water source is known as the senior appropriator. This person may continue to use the full allocation of water in subsequent years, although rights may be lost for not using an allocation. Subsequent users are junior appropriators. In years when there is insufficient water, junior appropriators may not receive their full allocations.

The appropriation doctrine is accompanied by issues demanding legal assistance. Allocations that cross state borders may be governed by federal treaties and court rulings. Cities may purchase water rights from landowners in the countryside leaving subsequent landowners without water. In some states, public sentiment may favor the reallocation of water from agricultural uses to other public needs. Another issue is retaining sufficient surface waters for recreational and scenic purposes. States continue to grapple with ideas to amend water usage rules to maximize the beneficial use of scarce water resources. Issues involving transfers of water rights may require careful legal analysis of competing interests and legislative pronouncements.

Environmental Issues

Producers have a responsibility in disposing of their byproducts and wastes responsibly so that they do not adversely affect others. Given damages that may be caused by pollutants, numerous environmental laws have been enacted and many apply to agricultural production (Centner, 2004). In pursing their activities, agricultural producers must desist from practices that release pollutants in violation of federal, state, and local environmental laws and regulations.

Turning to water quality, agriculture is listed by the US Environmental Protection Agency (EPA) as the major polluter of streams and lakes in the country. Under the US Clean Water Act, EPA has adopted numerous regulations that address the impairment of water quality by agricultural activities. Federal law distinguishes point sources of pollutants from nonpoint sources. Any point-source discharge of pollutants into federal waters needs a permit. Nonpoint-source pollution is regulated by the states.

A major issue involves pollutants from CAFOs. CAFOs are listed as point sources of pollution so that any CAFO with a discharge of pollutants into federal waters needs a National Pollution Discharge Elimination System permit. As a result of litigation commencing in 1989, EPA agreed to develop rules for CAFO discharges that would comply with the Clean Water Act. In 2003, 2008, and 2012, EPA adopted revised regulatory provisions for CAFOs. Agricultural lawyers continue to advise CAFO operators on the requirements delineated by the regulatory and judicial changes to the federal provisions.

Producers being charged with an environmental violation often employ legal counsel. Governments may assess considerable penalties for noncompliance. For example, an operator of a CAFO making a false statement in applying for a National Pollution Discharge Elimination System permit may be fined up to $10 000. An operator making an unauthorized discharge may be fined up to $37 500 per day (Centner and Newton, 2011).

Unacceptable air quality is also an issue that some agricultural lawyers may be called to address. Many CAFOs release significant quantities of air pollutants. Some states have decided that potential health problems associated with hydrogen sulfide, ammonia, and particulate matter releases from CAFOs merit regulation (Endres and Grossman, 2004). Agricultural lawyers can help clients meet requisite air quality controls and respond to enforcement actions.

Another air quality concern involves too much particulate matter in rural areas. Owing to vehicles on dirt roads and farm machinery in fields, considerable dust pollutes the air. Agricultural interest groups are seeking new legislation to relax air quality standards in rural areas. In 2011, bills were advanced in Congress to enact a 'Farm Dust Regulation Prevention Act' to enable state and municipal governments to exempt qualifying particulate matter from federal air quality controls. Under the provisions of the bills, mining, petroleum exploration and extraction, smelting, power generation, hydraulic fracturing, and other commercial and industrial activities would be able to release greater quantities of carcinogenic heavy metals in rural areas. The adoption of one of these bills might be expected to generate considerable work for attorneys in developing local regulations and responding to alleged violations.

Most agricultural producers take efforts to conserve their soil resources and seek guidance when the federal government introduces a new conservation program. The enactment of the Food Security Act of 1985 ushered in voluntary stewardship practices for private lands. Agricultural lawyers were called on to help clients discern the meaning of the swampbuster and sodbuster provisions of the Food Security Act in relation to the client's eligibility for benefits under other federal programs. Producers also considered whether to participate in the Conservation Reserve Program under which acreage is set aside from production in exchange for annual rental payments from the government.

Legal counselors may work with producers in analyzing the merits of participating in a number of federal environmental programs. These include the Environmental Quality Incentives Program, the Conservation Stewardship Program, and the Wetlands Reserve Program. However, despite many years of conservation efforts, agriculture remains a significant source of pollution of our nation's rivers and streams. The voluntary approaches for the adoption of stewardship practices have not provided lasting environmental protection. Future proposals to reduce pollution may be expected and legal counsel may assist producers in making decisions that will enable them to comply with new restrictions.

Agricultural producers may need the services of an agricultural lawyer to respond to allegations of damages accompanying the use of pesticides. Spray drift, the physical movement of pesticide droplets or particles through the air to any nontarget site, may cause problems when different crops are grown in close proximity. Agricultural attorneys may be called on to address allegations of drift damages in lawsuits based on trespass, nuisance, and negligence. Remedies under state law vary considerably given antinuisance protection and distinctions under trespass law for intangible drift.

Producers may also file a lawsuit against pesticide manufacturers for damages because of pesticides not performing as intended. Although the Federal Insecticide, Fungicide, and Rodenticide Act offers considerable protection for manufacturers of registered pesticides, producers are able to claim violation of state law labeling requirements if they are equivalent to federal misbranding provisions. Producers may also seek damages for crop losses under allegations of defective design, defective manufacture, negligent testing, and breach of express warranty. Lawsuits require considerable legal and scientific expertise to establish or disprove liability.

Agricultural lawyers may become involved with issues involving climate change. Although temperature and rainfall changes affecting crop production receive considerable attention, regulatory efforts to reduce greenhouse gas emissions affect agriculture. Producers may need to change practices to contribute to international efforts to address climate change (Hamilton, 2011b).

Other Issues

Agricultural lawyers have become involved with and provide advice on numerous other issues affecting agriculture. These efforts are important in helping agricultural producers develop and maintain viable business operations, respond to social expectations, and adjust their operations to changes in technology and the marketplace. Issues include food safety, genetically modified seeds, organic production, controlling diseases, migrant labor, animal welfare, energy, and local food production.

Food safety has become an important concern for many people, and numerous federal, state, and local regulations have been enacted to help guarantee safe food supplies. Some laws prescribe requirements that help guard against unwholesome foods and others provide for the inspection of food items and businesses processing food products. Federal agencies with food safety oversight include the Food and Drug Administration (part of the US Department of Health and Human Services) and the Food Safety and Inspection Service (part of the US Department of Agriculture). Many states have their own food safety provisions and inspection programs.

Outbreaks of food-caused illnesses show the need for food safety regulations. Although governments are in charge of prosecuting persons and firms that violate laws in placing unwholesome foods in the marketplace, legal counselors may be called to offer advice to persons injured by unwholesome food items. Counselors also help clients meet the regulatory requirements. This may include determining if a regulation applies to a client's activities, helping farm businesses comply with applicable regulations, or responding to allegations of a failure to comply with safety requirements.

A special food safety issue involves the sale of raw (unpasteurized) milk. To safeguard public health, federal law

precludes the sale of raw milk across state borders. However, a number of state legislatures have passed laws to allow the intrastate sale of unpasteurized milk. Legal counsel can help producers recognize the liability risks of selling raw milk and help them comply with the legal proscriptions.

Biotechnology and genetically modified seeds have revolutionized agriculture. Owing to seed patents, plant variety protection certificates, trade secrets, and licensing agreements, firms that develop seeds have property rights that may preclude others from adopting these innovations. Every genetically engineered organism needs a permit before it is introduced into the environment, with the Animal and Plant Health Inspection Service overseeing the permits. Agricultural lawyers may be called to offer advice to producers on the meaning of the intellectual property rights held by companies selling seeds. They may also become involved in lawsuits against agricultural producers over the infringement of patent rights.

Under US law, seed companies can sell patented seeds conditioned by a technology licensing agreement under which the seller expressly retains ownership of the genes and gene technologies (Endres, 2004). The agreement can preclude the buyer from saving any seed for planting the following season or from supplying seed containing protected genes to others. Agricultural producers who save seed for planting a subsequent crop despite their agreement to the contrary can be sued and held liable for the infringement of the seed company's rights.

A more disturbing problem is whether a farmer should be liable for infringing a seed developer's rights when pollen from genetically engineered plants is carried to conventional plants and protected genetic markers are found in the genes of the conventional plants. Under a Canadian lawsuit, a farmer was liable for patent infringement because patented genetic sequences were present in the farmer's crops because of pollen drift. Agricultural producers may face a patent-infringement lawsuit because of pollen from another producer's genetically engineered crops being detected in their crops. Aggressive enforcement of patent rights by seed developers means producers must respect established property rights.

Governmental efforts to control the introduction of foreign pests and disease outbreaks are important to agricultural production. To control the dissemination of a new disease, governments can destroy property exposed to the disease without compensation and quarantine animals. Given recent occurrences of citrus canker, citrus greening, mad cow disease (bovine spongiform encephalopathy), avian influenza, and H1N1 (swine) flu, governments have sometimes taken strong actions to eradicate a disease. Questions arise about who should pay for property that is destroyed or damaged by governmental actions (Centner and Ferreira, 2012).

Agricultural lawyers advise governments and producers on their rights concerning the destruction of diseased property. Under American jurisprudence, property owners have implied obligations not to use property in a manner injurious to the community. Simultaneously, however, federal and state constitutions require governments to pay for property taken for public use. Methods and programs to control disease may involve incentives for producers to invest in disease-prevention measures so that diseases do not become established. Disease eradication is important because it can reduce the need for pesticides and can lower costs of production.

Sources of manual labor continue to be important for agricultural production and producers are challenged by legal prescriptions governing laborers. Producers may need counsel to advise them on practices necessary for compliance with the law, particularly with respect to workers from foreign countries. Owing to exceptions under the Fair Labor Standards Act, agricultural workers may be exempt from minimum wages and overtime. Under the Migrant and Seasonal Agricultural Workers Protection Act, workers are entitled to prompt and full payment for their labor and safe, healthy housing. Aggrieved workers are able to bring lawsuits for damages or injunctive relief. However, an exception for small enterprises means that many workers are not protected. Controversy also exists about whether employers are responsible for workers' preemployment expenses including transportation, visa, and recruitment costs.

Producers who cannot find sufficient domestic workers may be able to bring nonimmigrant foreign workers to the US under a guest worker program. Program requirements vary and may require a showing that there are not sufficient workers willing and qualified to perform the seasonable labor needs. Another requirement may include documentation that the foreign workers do not adversely affect the wages and working conditions of similarly employed US workers. Programs often have requirements concerning housing, cooking facilities, and sufficient hours during the contract period. Workers may be granted a visa for a limited amount of time and may be precluded from seeking alternative jobs.

Producers are also often confronted with undocumented aliens seeking work. With an absence of proper documentation, it is illegal to employ these persons. The Immigration and Nationality Act requires employers to verify eligibility of individuals to be hired. Owing to dissatisfaction with rules for nonimmigrant foreign workers and undocumented aliens, Congress will debate this issue and may pass new legislation so that producers will need to make adjustments to their employment arrangements.

Concerns about illegal immigration and the lack of jobs for Americans have led some state legislatures to take actions to prohibit undocumented aliens from working within their borders. States have enacted laws with penalties for employers who fail to verify employment eligibility and for harboring undocumented aliens. Furthermore, an alien's failure to carry a registration document may be a state offense. Agricultural attorneys can help producers and workers in meeting the requisite legal requirements.

During the decade of the 2000, animal welfare issues became important to production practices in the US and Western Europe. Concerns about the ethical treatment of animals led animal rights groups to advocate legislation requiring more space for animals confined in cages and crates. The legislation affects producers of sows, chickens, and veal calves. Furthermore, because consumers want animals to be humanely treated, large food marketers and restaurant chains began adopting requirements under which producers must adopt space requirements. More and more companies are including animal health provisions in contracts with agricultural producers, employing veterinarians to provide care to animals at

producers' farms, conducting audits of producers' premises to check on such things as animal access to food and water, and monitoring worker training.

In 2011, the United Egg Producers and the Humane Society of the US agreed to work together to push for federal legislation regarding space requirements for hens producing table eggs. Proposed legislation would establish required floor space per hen. Individual states would be precluded from adopting space requirements in addition to or different from those set forth in federal law.

Public sentiment also raises questions about whether producers of animals for food should use husbandry practices that cause excessive pain to their animals. Husbandry practices involving tail docking, castration without an anesthetic agent, and beak trimming of poultry are controversial because of the public perception that they cause excessive suffering to the animals. California has banned tail docking of cattle. Individual US state legislatures are considering legislation to limit husbandry practices associated with pain.

Another development involves state legislative initiatives by agricultural interest groups against undercover operations by animal activists who fraudulently gain entry to facilities and subsequently distribute unauthorized information or images. Legislative proposals labeled as 'Ag Gag' laws are being introduced to limit these fraudulent activities. Although abuses have occurred with the dissemination of false information about agricultural producers, concern also exists that 'Ag Gag' laws stifle the exposure of inhumane and illegal practices. Provisions of some laws may also interfere with the freedom of speech.

The agricultural industry is concerned about energy and the production of biofuels as a source of energy. Congress has altered the face of rural America by deciding that the country needed to encourage the use of renewable energy sources, including the use of agricultural crops for ethanol and biodiesel production (Grossman, 2010). In 2012, approximately 40% of the nation's corn crop was used for ethanol production. Agricultural lawyers offer advice to Congress, producers, and others concerning the impact of various energy policies that affect the use of farmland.

The decade of the 2010 is one in which many Americans are asking what can be done to improve access to healthy food and help local communities. Local food production and direct farm marketing have been proposed as ways to improve access to healthy food and help rural communities (Hamilton, 2011a). Some people view the local production of food as a public service to their community and are motivated to participate despite the unprofitability of the enterprise. Others advance the idea that eating local fresh produce may help address obesity.

A locavore movement involves consumers buying locally produced food to garner freshness, support their local economy, and develop social connections to local food producers. By encouraging local agriculture, food consumers see themselves as helping to preserve nearby farmland for agricultural and recreational use, wildlife habitat, and wetlands. Food hubs are being organized to coordinate production and marketing of local foods to meet consumer demands.

Another justification for supporting the local food movement is based on a premise that less greenhouse gas will be produced if food products do not have to be shipped long distances. However, the transport of food to market may constitute $< 5\%$ of the food's life-cycle greenhouse gas emissions. Owing to the small scale of many local producers, the production of local foods may release as many greenhouse gas emissions as imported foods produced at larger, more efficient farms.

To assist entrepreneurs who desire to commence or expand local food production, agricultural lawyers can help with the establishment of business firms and contractual arrangements. Lawyers can also suggest practices to enhance the financial viability of local food efforts. One idea is to assist clients in devising a common-interest community that includes a governance mechanism for decision-making and a revenue device for spreading costs and income (Schutz, 2011). Consumer support for local foods suggests that the locavore movement will be important for many communities.

Conclusory Comments

Although this article has focused on legal issues in the US, several topics may be expected to be important internationally (Cardwell, 2004; Rogers, 2008). Agricultural lawyers in most countries assist producers with legal documents concerning land, contracts, and financing arrangements. They also may assist in restructuring operations to take advantage of support programs and marketing opportunities. In other cases, counselors are involved in land reform.

Agricultural lawyers might be involved in three policy issues that continue to affect world food supplies and the provision of food to the hungry. Food safety, food security, and trade impediments are matters that governments can address to facilitate better living conditions.

People all over the world are concerned about food safety. The agricultural law community can help governments develop appropriate regulatory provisions to reduce risks of contamination during the production and marketing of food products. Moreover, persons involved in marketing unwholesome food products need to be held accountable for damages.

Food security continues to be a problem not only in the developing world, but also for many people in the developed world. The availability of sufficient food supplies may be exacerbated by climate change. The legal community needs to foster programs and ideas to help get food to persons who are hungry.

Legal counselors may also need to become involved in opposing regulations that constitute barriers to international trade. Countries are able to adopt phytosanitary measures relating to food safety and animal health with respect to imported pests and diseases. However, protectionist interest groups sometimes convince governments to adopt regulations such as domestic subsidies for agricultural products, import quotas, and standards that differentially impact foreign suppliers. A major source of disagreement involves import restrictions on food items produced from genetically modified organisms. Are the restrictions a justifiable precautionary approach to a risky technology or an unjustifiable barrier to trade? Another potential barrier may be an environmental

measure to promote a domestic environmental norm at the expense of foreign producers. Potential barriers involving animal welfare may also interfere with trade.

Agricultural lawyers are instrumental in helping clients and governments with activities involved in with supplying safe food products. Although lawyers' activities vary in different countries, the topics addressed by American agricultural lawyers offer ideas for augmenting food production and food safety. Specialized agricultural lawyers can become involved in marketing arrangements and a regulatory framework that fosters reasonable food prices and minimizes risks of unwholesome food products.

Glossary

Biological innovation Improvements in seed, fertilizer, and cultural practices directed to adapting plants to new environments, combating pest threats, and increasing yields and labor productivity; also improvements in breeding stock, feeding practices, and health directed to increasing livestock productivity.

Combine A mobile harvesting machine that combined the cutting and threshing operations into one device. The early combines were mammoth machines often powered by about 40 equines.

Cotton gin A machine perfected by Eli Whitney in 1793 to separate the seed and fiber in Upland cotton.

Cradle A scythe with a small wooden frame attached at the rear of the cutting blade used to harvest small grains. The frame caught cut grain and stalks helping to prevent the grain from shattering. In North America this device replaced the sickle and scythe in the late eighteenth century. It in turn was replaced by the mechanical horse-drawn reaper beginning in the late 1830s.

General purpose tractor This machine which first appeared in 1924 spaced the wheels so that the tractor could work among growing crops. This was one of many innovations that significantly increased tractor versatility and which contributed to its diffusion.

Lister (also called a middlebuster) A lister is a plow that throws the soil on both sides of the furrow.

Mechanization Mechanization involved the replacement of simple hand tools and human power by more complicated machinery powered by animals, fossil fuels, and electricity.

Sea Island cotton Very long staple, high quality, cotton introduced into North America in the latter decades of the nineteenth century. It was primarily grown in a limited range along the coasts of Georgia and South Carolina. It commanded a premium price.

Upland cotton Short and medium staple length cotton grown in more varied conditions than Sea Island. American breeders significantly improved Upland cotton varieties in the nineteenth century. The seeds of most upland cotton varieties cling to the fiber making it difficult to remove the seeds without an improved gin.

This article highlights one of the epic stories in world history. In the nineteenth and twentieth centuries, powerful forces continuously reshaped world agriculture. In the US, the nineteenth century witnessed the addition of hundreds of millions of acres of farmland, and millions of farms and farmers. With this expansion, the farm population grew. It approached its zenith around 1910, but the relative size of the farm population was shrinking. In 1790, roughly 90% of the US population lived in rural areas and most of these people were farmers; in 1910 approximately 35% of the US population resided on farms. By 2010, only 1.5% of the labor force worked on farms. In the twentieth century, the amount of farmland changed little, but the growing gap between farm and nonfarm incomes and opportunities contributed to a massive exodus from America's farms. In the 1950s alone, more people moved off farms than resided on farms in 2000.

Throughout most of human history, and in large parts of the world today, the dominant concern has been how to produce enough food and fiber to feed and clothe the population. Over the course of the past 200 years in the US, the creation and diffusion of new technologies fundamentally changed agricultural constraints and dramatically reduced the real price of most farm products. The innovations can be grouped into two distinct groups: mechanical technologies and biological technologies (meaning improved fertilizers, seeds, irrigation, and the like). In this article the authors focus on some of the landmark mechanical developments of the last two centuries. Mechanization involved the replacement of hand tools and human power by machinery and draft power (first from animals and later from fossil fuels and electricity). These changes typically increased the amount of land one worker could cultivate and harvest, and they often also increased land yields by allowing more timely and more thorough work. These changes dramatically increased farm productivity and changed the nature of farm work. At the millennium, the typical American farm worker produced over 15 times as much output as a worker in 1900 and 30 times as much as in 1800 (Weiss, 1991, p. 6).

Grain Harvesting and Threshing Machines

The mechanical revolution in American agriculture is symbolically identified with the introduction and diffusion of the threshing machine and the mechanical reaper (along with its close cousin the mechanical mower). These machines were marvels in their day, and people would travel for hours just to be able to watch early prototypes in exhibitions. As an indication of their significance, Cyrus McCormick, the principal inventor of the reaper, was acclaimed as the 'man who made bread cheap.' Dramatically lowering the cost of grain in an age when bread was a dietary staple and many people spent over one-half of their income on basic foodstuffs was indeed a significant achievement.

 doi:10.1016/B978-0-444-52512-3.00236-9

The threshing machine, which separated small grains (wheat, oats, barley, and rye) from the stalks and husks, represented the first great step in grain mechanization. This advance dated back to the work of Scottish engineer Andrew Meikle in the 1780s. Before the diffusion of the thresher, farmers had to beat the grain with a flail. In some areas, farmers laid the cut grain and stalk on hard ground and then trampled it with draft animals to dislodge the grain. This task often extended for months following the harvest. In 1791, both Thomas Jefferson and George Washington viewed a threshing demonstration, and Jefferson was so impressed that he ordered one of Meikle's models from London. By 1796, Jefferson operated three threshers at his Monticello estate. The spread of threshers in England in the 1820s contributed to widespread rural uprisings, commonly known as the 'Captain Swing' riots. Farm workers, threatened by the loss of employment, resorted to smashing machines and threating farmers. One usually thinks of innovations being more likely to gain a foothold if they address a peak load constraint, such as exists during the grain harvest. But the thresher replaced labor during the off season when wages were relatively low, and when the rioting wage-workers in England had few alternative employment prospects. In the North American grain belt, where owner-occupiers and family members performed much of the farm work, the adoption of the labor-saving threshing machine was generally welcomed, not resisted.

As with other machines, widespread diffusion came after many improvements, both large and small. One major innovation came in the mid-1830s with the addition of a winnowing mechanism. Before this, farmers had to winnow the threshed grain by throwing it into the air in a natural breeze or use a fan to create airflow. The heavier grain would fall separately from the chaff. Another avenue of innovation was to improve the treadmill powering the machine. In 1830, John and Hiram Pitts, originally from Maine, patented a device with a 'railway' tread power. In 1834, they added an apron carrier, and by 1837, the twin Pitts brothers had created what is often considered the first commercially successful American-made thresher. Many other companies manufactured threshers in North America, including J. I. Case, the Wood brothers, and Aultman. Machines came in many sizes. In some communities, neighboring farmers organized local threshing bees, in which the machine was owned by one farmer and others contributed labor and draft stock in exchange for the services. In other places, threshing was done by itinerant private contractors who rented machine services to farmers who provided much of the labor and some of the horses to power the operation. On the giant grain ranches in California in the 1870s, a typical threshing crew might have consisted of 18 men, including one engineer, two feeders, one sack sewer, and 14 laborers. Over the next decade several labor-saving inventions, such as the derrick table to convey the grain from the stack to the thresher and a self-feeder, reduced the labor requirement by almost a third. The use of threshers allowed farmers to process their cut grain sooner after the harvest, thereby reducing exposure to damage from insects and adverse weather. By reducing the need for labor over the fall and winter months, the thresher actually increased the relative peak load labor demand during the harvest season. This problem of the seasonality of labor demand was addressed in part by the mechanical reaper.

For millennia, small grains had been harvested with sickles. Men and women had to stoop over, grab a clump of stalks with one hand and then cut it with the sickle. The grain was then gently laid on the ground so that seeds did not shatter. Scythes (a tool with a long handle and a curved blade approximately 3 feet long) were used to mow grass and harvest grains. A harvester using a scythe could stand erect and work much faster, but grain was more apt to shatter. In the late colonial era, American farmers began adding a wooden frame to the rear of the blade to catch the cut grain. This tool was called a cradle. With the turn of the arm, the cradler could lay the cut grain to the ground thereby reducing shattering. One cradler could do the work of several workers with sickles. With the advent of the cradle, harvesting changed from a task performed by both men and women to what was principally a man's job. There was still plenty of work for women and children: the grain (still attached to the stalk) needed to be gathered into small bundles and stacked in a shock to dry. Before the mechanical thresher, the grain would then be threshed and winnowed by hand (Rogin, 1933).

Reapers in the US date to the patents of Obed Hussey (1833) and Cyrus McCormick (1834). Their machines represented the first steps in a process which would revolutionize the harvesting of small grains. The reaper was refined throughout the next several decades, and its key features were embodied in the harvesters, headers, and combines that succeeded it into the fields. The essential elements of early reapers as they emerged in the 1850s included a cutting bar with reciprocating knives. The bars ranged from 4 to 6 feet in length and extended out one side of the machine. The grain fell onto a platform from which it was manually raked to the ground – at first by a worker who trotted next to the machine. A reel rotated in front of the cutting bar to push the grain into the knives. In addition to a driver and a raker, a crew of approximately six workers was needed to bind and shock the cut grain. Most early reapers required four horses. As machine draft declined with improved design and construction, two-horse machines became the rule. The basic machine of the 1850s probably did the work of five to seven men working with cradles. In addition, the reaper technology was adapted to developing specialized mowers to cut grass for livestock. This greatly reduced the labor required to maintain milk cows and led to an increase in dairy production (Hutchinson, 1930, pp. 250–275, 366; Olmstead, 1976).

Reaper and mower manufacturers developed some of America's first large integrated factories, and they eventually catered to a national and even a world market. McCormick, the most important of the early producers, moved his operation from Virginia to Chicago in 1847–48 to be closer to the growing Midwestern market; in 1858 he made over 4500 machines. Many other producers entered the market, with several surpassing McCormick. In the 1850s and 1860s, total output soared. Improved production processes and fierce competition drove down real machine prices and output reached 80 000 machines by 1865. At the same time, machine quality continued to improve.

By early 1860s, many reapers were equipped with automatic rakes that neatly deposited bundles of wheat on the

Table 1 Acres of small grains harvested per worker day

Method	*Acres/day*
Scythe	1/3–1/2
Cradle (late eighteenth century)	1
Reaper (1833)	1.5–2
Self-raker (1854)	2–2.5
Self-binder (1881)	10–12

ground to be gathered and shocked. This saved the labor of an additional worker. In the 1870s, an ingenious twine binder was attached to new reapers. This tightly bound the bundles, making them easier to shock. Table 1 charts the increase in acreage harvest per day of work associated with the adoption of more advanced grain-harvesting techniques.

As is common with many paths of innovations, the rate of advance in productivity during the improvement phrase (from reaper to self-binder) was greater than during the initial invention phrase (cradle to reaper). But taking this first step was necessary to create the platform for the subsequent improvements. In the East and Midwest, twine self-binders remained the dominant harvesting technology well into the twentieth century.

But in California innovation took a different path, which would eventually change harvesting around the world. Several features of California agriculture – high wages, large-scale farms, and a distinct climate – help explain the different course of harvesting innovation. In addition, Californians learned how to manage large teams of eight or more animals – a skill alien to most farmers in other regions. For these reasons, California farmers increasingly adopted 'headers' in the 1860s. A header had a high cutting bar so that it only cut the top of the plant. The cut grain was then transported on a continuous apron to a wagon or header box. Headers had longer cutting bars than reapers and, hence, greater capacity, but the most significant advantage was that headers eliminated the need for binding. This feature saved the labor of about five binders. The initial cost of the header was approximately 50–100% more than the reaper, but its real drawback was that it required the grain to be fully ripe and dry at harvest-time. This involved enormous risks in the humid Midwest, but not in California.

Once a farmer had a header, it was natural to run a thresher next to it – the two machines worked in tandem. Many inventors in the East and Midwest had attempted to perfect a machine that both reaped and threshed. One of the most successful was Hiram Moore's combine (built in 1835). Moore operated his machines on his own and neighboring farms in Kalamazoo, Michigan for about five seasons, yet it did not gain lasting acceptance in the Midwest. Combining suffered from the same problems with moisture that plagued heading in humid areas. In 1853, Moore's invention was given new life when his son operated a model on a farm near San Jose, California even though it was destroyed by fire after harvesting only 600 acres. From this inauspicious start, the combined harvester business gradually took root in California. By the mid-1880s, Stockton, California became the center of production and home to firms such as the Holt Company and the Stockton Combined Harvester and Agricultural Works (Olmstead and Rhode, 1988).

The California combines were much larger than any equipment common in the Midwest during the nineteenth century. Ca. 1900, the most popular self-binding reapers had 6-feet cutting bars, with a capacity of 10–12 acres per day using 2–3 horses. By this time, the standard California combine had a cutting bar of 16–22 feet, a daily capacity of 22–30 acres, and required a team of 25–35 horses. The largest combines adopted in the Midwest in the 1920s and 1930s were smaller than the standard California machine of the 1880s. As a rule, farmers east of the Rockies seldom teamed more than eight horses and did not use large-scale equipment in the field until after the introduction of the gasoline tractor.

The enormous teams in the West posed a threat if the animals bolted – runaway teams destroyed many combines. The search for a solution led George Berry of Visalia to develop the first steam traction combine in 1886. This combine had a massive 40 feet long cutting bar and supplied itself with fuel, burning the cut straw. Many manufacturers followed Berry's example, and throughout the 1890s both Daniel Best and Benjamin Holt improved their steam tractors to pull ever larger combines. These machines never gained wide acceptance, in part because of the fire danger. But a lasting spin off of the steam traction engine era was the development of the gasoline powered tracklaying tractor.

The evolution of the combine involved making the machines smaller and more versatile, and perfecting its components for use in harvesting corn, beans, peas, and other crops. This process started during WWI, when gasoline tractors began to replace steam tractors and horses for propulsion, and when internal combustion engines were added to drive the cutting and threshing equipment. By the late 1920s, models with 8 and 10 feet cutting bars with the machinery driven by the tractor's power take-off were widely available. This allowed the combine to be profitably employed in the grain-growing regions east of the Rockies. In Kansas, combines were an infrequent sight before 1918. They harvested approximately 30% of the state's wheat by 1926 and 82% by 1938. By this date, combines harvested about one-half of US wheat acreage. The next big advance was the arrival of the self-propelled combine. With the tractor built into the machine, one worker could operate both the combine and tractor. In the 1940s, as specialized custom harvesting became more widespread, there was a reversal in the trend toward smaller machines. The share of all US wheat acreage harvested by combines rose to more than 75% by 1945 and nearly 95% by 1950 (Brodell, 1952, pp. 2–5; Quick and Buchele, 1978).

The combine also adapted to harvest other crops. By 1950, combines harvested almost two-thirds of the nation's oat acreage and almost all soybean acreage. The advent of improved corn head attachments in the early 1950s allowed combines to become the dominant maize-harvesting technology by the mid-1960s. With the vast reduction in the need for seasonal harvest labor, many farm families, perhaps aided by a few hired workers or a custom operator, could now manage the harvest. Farm life was changed dramatically. Perhaps the most appreciative were the farm wives, who no longer had to cook for the armies of migrants who followed the harvest.

Tractors

As one has seen, the quest to apply mechanical power to the farm long predated the gasoline tractor. Farm steam engines probably first made their appearance in cotton gins, and mobile engines were adapted to power threshing machines in the late 1840s. A number of early inventors constructed massive steam plows. In 1858, Joseph Fawkes exhibited a steam plow at the Illinois State Fair. In the decade following the Civil War, many manufactures ventured into constructing prototypes. Philander H. Standish of Martinez, California was an important pioneer. On May 10, 1868, Standish patented a steam engine plow, and according to contemporary accounts actually plowed 100 acres with it. In 1868, a Standish steam traction engine named 'The Mayflower' drew huge crowds at the California State Fair. But for all the interest, the monster machine never was a mechanical or financial success.

An alternative was offered by the English cable system of plowing. The cable system consisted of two stationary steam engines located at opposite sides of a field. Steel cables attached to the engines pulled the plow across the field with the engines alternating the pulling. This method required five to eight men: a foreman, two engineers, one or two teamsters, and two plowmen. The cable plows were expensive, and the steel cables, which needed replacement roughly every year, cost between $600 and $900 each. The expense limited the market to a few experimenters with very large estates. A significant problem with the early steam traction engines was their reliance on the models built for steam threshing that made them unsuitable for plowing. The traction gears were not strong enough to pull the drawbar, the drive wheels were not large enough, the machines were difficult to operate, and the plows too often snagged in uneven terrain.

The 1870s and early 1880s were a period of experimentation, with no individual or model dominating. Gradually, through trial and error, various technological changes were made to increase the practicality of mobile steam plows. Two industry leaders emerged, both of which were located in Stockton, California and both of which were active in the early combine harvester industry. Daniel Best and the Holt Brothers both produced models with horizontal boilers. These weighed over 10 tons, could plow approximately 40 acres a day, and ca. 1890 sold for approximately $4500. Because they were so large and so expensive, their primary market was the large California wheat ranches. By 1890, eastern and Midwestern producers such as J. I. Case of Racine, Wisconsin were manufacturing steam traction engine plows. The Case machine was suitable for plowing, harrowing, hauling, running threshing machines and sawmills, rolling streets, and pulling combines as well as plows (Wik, 1953).

Steam traction engines could be built to run off of virtually any type of fuel. In the East, farmers often used coal and wood, but in the West the price of these fuels was generally so high that manufacturers constructed straw-burning engines. By the turn of the century, steam traction plows were established as an alternative to horse-drawn plowing in the West. In the East, steam plowing did not become popular until the early years of the twentieth century, with the advent of stronger and lighter weight engines. Everywhere, improved designs increased steam pressure and enhanced reliability.

The steam plows needed several men to attend them. A skeleton crew included the engineer, the fireman, and a man with horses to haul fuel and water. The engineer steered the plow and was usually in charge of the plowing operation. Probably the most crucial job was that of the fireman. Great skill was needed to keep the fire burning steadily so that the steam pressure was kept constant all day long and the boiler was not allowed to run dry. It was also the most uncomfortable job. In warm weather, the fireman was warmer still, standing only a few feet from the firebox heated to nearly 2000 °F. In addition, the water in the boiler, at 325 °F, radiated still more heat, 'drenching the fireman in his own sweat, and perhaps reminding him of Hades itself.' The 'water-boy' or hauler position also required a measure of responsibility. With a boiler requiring 2000 gallons per day and fuel of a ton of coal or its straw equivalent, the hauler was kept busy. The boiler had to be kept full of water or risk the danger of explosion. Water quality was a problem, especially in the arid West. The relatively scarce surface water supply forced western operators to rely on artesian well water, leading to the problem of 'hard' or alkali water. The calcium, sodium, and magnesium in the water disagreed with the digestive system of the steam engine. These minerals coated the insides of the boiler and flues, often ruining the machine within 2 years. Another major drawback of the steam traction engine was the tendency to emit sparks from their smokestacks, particularly when using straw for fuel. This created an obvious fire hazard.

By the early 1900s, steam traction plowing reached its zenith, but even in the West, where they were most common, steam plows were never replaced draft animals as the primary source of farm power. The diffusion of steam plows represented an important step in moving American agriculture out of the horse age by paving the way for the acceptance of the gasoline tractor and other types of farm machinery. The giant traction plows created excitement and an interest in mechanization, and many farmers developed skill in operating and repairing the machines which would prove handy for operating the next round of inventions. Moreover, many steam traction plow companies would become innovators in the application of gasoline engines to agriculture.

The internal combustion engine was about to forever transform rural America. This took several forms. The automobile and motor truck helped integrate the farm into the broader world. On the farm itself, tractors increased the horsepower available to farmers and increased farmer productivity, drastically reduced the need for seasonal labor, and changed social relationships. The integration of the tractor as an essential part of other types of equipment, such as the self-powered combined harvester and the mechanical cotton picker, magnified the tractor's impacts.

Patterned after the giant steam plows, the early gasoline tractors were behemoths. They were suitable for plowing, harrowing, and belt work; but they were not useful for cultivating in fields of growing crops or for powering equipment in tow. The gasoline engine offered numerous advantages over the steam engine. It was less prone to explosion and, therefore, much safer to operate, it did not require constant supervision, it provided high power at a much lighter weight, it required only one person to operate, thereby saving greatly in labor costs, it eliminated the problem of poor water and lack of

water, and it was not an ever-present fire danger; in short, it was more economical and a great deal safer. Between 1910 and 1940, innovations vastly improved the machine's versatility and reduced its size, making it suited to a far wider range of farms and tasks. At the same time, largely as a result of progress in the new mass production industries, the tractor's operating quality greatly increased, and its price fell.

Several key advances marked the otherwise gradual improvement in tractor design. The Bull (1913) was the first truly small and agile tractor, Henry Ford's popular Fordson (1917) was the first mass-produced entry, and the revolutionary McCormick-Deering Farmall (1924) was the first general purpose tractor capable of cultivating amongst growing row crops. The Farmall was also one of the first machines to provide a power-takeoff, which transferred power directly to implements under tow. A succession of secondary innovations such as stronger implements, pneumatic tires, improved air and oil filters, and the Ferguson three-point hitch and hydraulic system vastly increased the tractor's life span and utility. These changes yielded enormous returns. As an example, rubber tires increased drawbar efficiency in some applications by as much as 50%, reduced vibrations thereby extending machine life, and enhanced the tractor's usefulness in hauling (a task previously done by horses).With greater mobility, farmers could more easily use a tractor on widely separated fields (Gray, 1954; Williams, 1987).

Again, a separate innovative path developed in California. The heavy steam tractors and early wheeled gasoline designs were not suitable for the enormous ranches in the newly reclaimed lands in the vast Sacramento-San Joaquin Delta. Even horses had difficulty working on these highly productive but soft peat soils. The solution was a tracklaying or crawling tractor – what would become known as a Caterpillar design. The principle of the tracklayer was to widen the area of contact to spread the weight of the machine and increase its traction. In the culmination of several years of effort, Benjamin Holt successfully tested a 40 hp crawler on a delta island near Stockton in 1904. Although the crawlers were first designed to solve an essentially local problem, this innovation was of global significance. The Caterpillar Tractor Company (formed by the merger of the Holt and Best enterprises) would build larger more powerful equipment that rapidly spread throughout the world (Olmstead and Rhode, 1988).

Knowledgeable observers argued that these improvements in tractor design greatly increased performance and durability. As an example, Roy Bainer, one of the deans of the agricultural engineering profession, was an early tractor adopter as a young man. He noted that without improved air filters his machines lost power and needed a valve job within a year of entering service. He also maintained that the Ferguson hitch revolutionized the tractor's capabilities. The rapid diffusion of some of the changes is consistent with Bainer's informed view. The standard-wheeled models fell from approximately 92% of all tractors sold for domestic use in 1925 to approximately 4% in 1940. Conversely, general-purpose tractors, which were first introduced in 1924, composed 38% of sales in 1935 and 85% by 1940. In a similar fashion, within 6 years after the introduction of pneumatic tires in 1932, 95% of the new tractors produced in the US were 'on rubber.' By 1945, over 70% of all wheeled tractors on farms had rubber tires (McKibben and Griffen, 1938, p. 13; US Bureau of the Census, 1947, p. 13; Olmstead and Rhode, 2001).

Developments since WWII have mostly refined existing designs by increasing tractor size and adding driver amenities, such as power steering and air-conditioned cabs. Farmers have come a long way from the time when they walked the fields behind horse-drawn plows. After remaining roughly constant from 1920 to 1940, the average horsepower of new tractors quadrupled between 1947 and 1977, reflecting a shift in farmers' preferences toward larger machines.

Figure 1 offers a view of the transition from equines to tractors in the US between 1910 and 1960. The number of farm horses and mules peaked at 26.7 million head in 1918, and the number of working animals (aged 3 and over) peaked in 1923 at 20.7 million head. After 1925, draft animal numbers steadily declined, falling below 3 million by 1960.

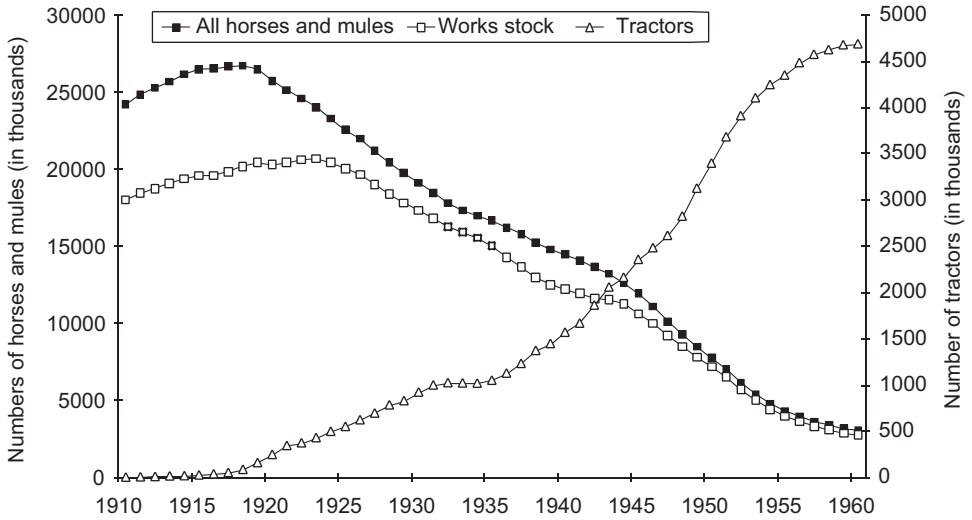

Figure 1 Number of draft animals and tractors in the US (1910–60). Reproduced from Olmstead, A.L., Rhode, P.W., 2001. Reshaping the landscape: The impact and diffusion of the tractor in American agriculture, 1910–60. Journal of Economic History 61 (3), 670.

The stock of tractors began to expand rapidly during WWI, rising to a plateau of approximately 1 million machines in 1929. A second burst of growth began in the late 1930s, leading the tractor stock to climb above 4.5 million units by 1960. The percentage of US farms reporting tractors rose from 47% in 1940 to 83% in 1954. The diffusion of the tractor exhibited significant regional variation, with the most rapid adoption in the West North Central and Pacific regions. The arrival of general-purpose tractors in the mid-1920s sped the pace of diffusion in the East North Central region. All regions experienced a slowing of diffusion during the Great Depression followed by an acceleration during and immediately after WWII. By 1950, the tractor had largely replaced the horse throughout the North, and was rapidly becoming a fixture in the South.

The simple measures of diffusion miss the tractor's impact on the total horsepower capacity available to farmers. The extra power gave farmers more versatility, especially in peak-load periods. Between 1910 and 1960, national farm draft power soared over four-and-one-half times, whereas cropland harvested remained roughly constant. Tractors accounted for approximately 11% of national stock of farm horsepower capacity in 1920, 64% in 1940, and 97% in 1960. Thus, compared with the percentage of farms reporting tractors, the measure of diffusion using power capacity started higher, and grew faster and more smoothly (Olmstead and Rhode, 2001). But as a share of new horsepower capacity, the movement to tractors was even faster. By 1930, tractors provided approximately 80% of the new horsepower adopted by farmers; and by 1940, the figure had risen to approximately 90%. Essentially farmers had a stock of the old form of power which remained available, but new investment went to machines not animals. The result was that the average price of draft animals fell. This price movement helped keep the animal mode of production competitive long after breeders dramatically reduced producing new equine capital.

The tractor's impact on labor and land use altered the course of American development. The decline in the farm population after 1940 represents one of the great structural shifts in American history. By 1960, tractors had reduced annual labor needs in agriculture by roughly 1.7 million workers; this represented over 25% of the total decline in farm employment since 1910. This makes the tractor one of the greatest labor-saving agricultural inventions of any age. The tractor also stimulated the growth in the average size of farms.

In recent years, policies have subsidized farmers to grow corn and other crops to produce ethanol. The idea is to substitute crops for oil. These policies would have to be expanded significantly to approach the land use patterns of the pretractor age. In fact, the tractor was one of the greatest land-saving innovations in the history of agriculture, allowing American farmers to convert approximately 80 million acres of cropland and another 80 million acres of pastureland from supporting draft animals into providing products for human consumption. To provide perspective, the cropland diverted represented approximately 25% of the US total. It was roughly equivalent to adding acreage equal to two-thirds of the cropland harvested in the entire territory of the Louisiana Purchase to the nation's effective land base. Much of the land previously used to feed draft animals went to feed dairy cows and beef cattle. But there is more: by allowing farmers to work better, the tractor had a direct impact on yields. Thus, one of the seminal mechanical inventions of all time was both a major labor-saving and land-saving innovation (Olmstead and Rhode, 2001). Overall, the tractor's impact on land use and productivity added significantly to America's agricultural surpluses, and surely depressed crop and livestock prices. This contributed to the great upheavals of the interwar years, and to pressure for government farm programs. By the 1930s, the acreage no longer needed to feed draft animals roughly equaled the acreage removed from production by the USDA's wheat, cotton, and corn programs (Olmstead and Rhode, 1994).

Tools for Tillage

The authors touched on tillage equipment in their discussion of tractors, but the developments in this broad category of implements deserves its own account. The objectives of tillage operations ca. 1930 included opening the soil so that rain could absorbed; limiting erosion; pulverizing the soil; integrating stubble, straw, and fertilizer; aerating the soil; tamping the soil; and destroying weeds and injurious insects. These various tasks led to the development of a wide variety of specialized tillage implements, namely moldboard plows, disk plows, listers, and several types of harrows (Davidson, 1931, p. 80).

The six decades before the Civil War witnessed vast improvements in cast iron and steel moldboards. Many farmers entered the nineteenth century with a one-handled ox-drawn plow which was made completely of wood, except perhaps for a small iron tip. This device lacked a moldboard to turn the furrow; it scratched the surface rather than plowed the soils. By contrast, the standard plow of the mid-nineteenth century was a balanced horse-drawn two-handled model, with a variety of interchangeable cast-iron shares and moldboards for different conditions. A notable step in this change was the 1837 invention by John Deere, a blacksmith from Grand Detour, Illinois, of a self-polishing cast steel plow. After moving to Moline, Illinois in the late 1840s, Deere began marketing his perfected steel plow in the Midwest. In that region, damp soils would cling to – rather that scour off – the moldboards of most previous types of plows. The smoothed surfaces of Deere's plows solved the problem of sticky soils. A related advance was the development and commercialization of chilled cast-iron plowshares by James Oliver of South Bend, Indiana in late 1850s and 1860s. In the late nineteenth century, wheeled models became common. Wheeled plows may be further distinguished along two lines: the number of bottoms and whether the driver rides or walks. Plows with more than one bottom are called gang plows; those with a seat for the driver, sulkies.

Over time there was a general movement toward larger implements, first for big teams of horses and the rare steam traction engines, and later for the revolutionary gas tractors. Tractors offered more power and speed than horses, thus requiring larger and stronger equipment to take advantage of the larger capacity and to withstand the increased stress. With the introduction of the general-purpose tractor and the three-point

lift system, the use of mounted tools, from plows to cultivators, soared. Since 1900, the manufacture of tillage equipment has followed a trend common to many industries. Seven or eight full-line companies, that is, producers of tractors as well as implements, have captured most of the market. These companies were, in order of importance (ca. 1935), International Harvester, Deere, Case, Oliver, Allis-Chambers, Minneapolis-Moline, Massey-Harris, and Avery. In 1937, these eight firms produced approximately 95% of the tractor plows sold in the US, nearly 80% of the disk and spring-tooth harrows, about three-fourths of the spike-tooth harrows, around two-thirds of the sulky plow and two-horse walking plows, and somewhat less than half of the one-horse walking plows.

As smaller tractors became popular after 1915, two- and three-bottom gang plows rose in significance. At first, horse-type plows often were adapted to two- and three-plow tractors, but the hitching arrangements and their ability to withstand the increased stress left much to be desired. For example, the first tractor plows were attached only with chains and were impossible to back up. More rigid hitches remedied this failing. Other improvements, such as heat-treated parts and stronger frames, made the plows more durable. Although the changes in design were relatively minor, the quality improvements were dramatic. A study by leading agricultural engineers judged the tractor plow of 1932 was about twice as good as that of 1910–14. With the advent of power lifts on tractors around 1930, plows mounted directly onto the tractor were adapted. The carriage or wheeled frame could be discarded, and lifting and adjustment performed mechanically. The introduction of impediments for the Ferguson three-point linkage system and hydraulic lift further increased efficiency (Bainer *et al.*, 1953, ch. 6). Tractor manufacturers saw the need to better match their machines and the equipment they towed, and many leading firms began to offer specially designed tillage equipment as early as the 1920s. This led to the integration of many equipment makers and tractor companies into full-line firms.

Besides improved plows, several other pieces of primary tillage equipment came into vogue in the late nineteenth century. One was the lister or middlebuster, which was essentially two moldboard plows set back-to-back to throw soil to both sides. Much like plows, listers were available in walking, riding, and tractor-mounted models. Disk plows also appeared by at the end of the nineteenth century. The disks were set at an angle both to the ground and the direction of motion. For tractor gangs, four to six disks were the most common. Replacing the share, moldboard, colter, and jointer of the moldboard plow with a rotating disk was first conceived as a means of reducing draft. But disks lacked the suction of the moldboard plow and needed greater mass to maintain penetration. The heavier frames and added weights increased the disk's draft. Disk plows do not turn the soil as thoroughly as moldboards. The choice of whether to use a disk or a plow often depended on the type of soil.

Three types of harrows were employed on American farms: the spike-tooth, the spring-tooth, and the disk harrow. The oldest of these is the spike-tooth harrow, which traces its ancestry back as far as the plow. The first spike-tooth harrows were purportedly of a triangular or 'A' configuration, reminiscent of the ancient Roman harrows. The triangular models continued to be popular for orchard and vineyard work, but for most applications these were replaced by rectangular harrows. Though less widely used, spring-tooth harrows also were adopted after their perfection in the 1870s. By 1896, John Deere was offering spring-tooth harrows that were similar to those used today. These harrows replaced the peg of the spike-tooth harrow with flat coiled steel teeth. Unlike the spike-tooth model that levels the soil, the spring-tooth variant is sufficiently aggressive to destroy weeds and to substitute for repeated plowing in many instances. It is principally used to prepare the seedbeds for row and truck crops.

The disk harrow has been uniquely adapted for cultivating, turning under cover crops, and incorporating fertilizer among trees and vines. Disk harrows and disk plows were different machines. The harrow is comprised of several gangs of 14–24 inch, relatively shallow concave disks that turn together. By contrast, the disk plow has a smaller number of larger, deeply dished disks which are independently mounted at an angle on a wheeled frame. (The vertical or one-way disk plow is something of a combination of the two with large disks turning as a unit mounted in a wheeled frame.) There were many harrow types, including a single disk, tandem or double disk, and offset disk. These had different disk arrangements, which turned the soil in different directions. In the 1890s, John Deere offered a reversible disk. In its closed form, the gangs were set as in a 'V' frame. But the gangs could also be extended outward and, though separated by several feet at the center, used to cultivate in orchards beneath the branches. The single gang of the 1890s with a large number of small closely spaced disks remained essentially unchanged for the next two decades. With the advent of the tractors, a second set of disks was added. These tandem disks harrowed more thoroughly and eliminated the need to make a second pass (Davidson, 1931).

Other implements evolved to plant, thin, cultivate, and distribute chemicals. These include broadcast seeders and drills for field crops, planters, and thinners for row crops, cultivators, fertilizing equipment, and sprayers for orchards and fields. There are two broad categories of seeders: those used in field crops such as the small grains – that is, principally broadcasters and drills – and those used in row crops such as corn, cotton, beans, and truck crops – that is, planters and, later, precision planters.

For early producers of field crops, the first group was, by far, the most important. Yet, the advantages of the drill were soon recognized. Drills look much like boxseeders except that they have furrow openers, seed tubes to deposit the seeds below the surface of the soil, and coverers. Both drills and the later boxseeders had force-feed mechanisms to regulate the flow of seeds from the hopper. Drills assured more uniform distribution and reduced the amount of seed needed by almost half. By the mid-1890s, single- and double-disk openers, which reduced draft requirements, came into vogue.

For row crops, both planters and cultivators reached a high state of development. Among the most versatile and widely used machines was the corn or cotton planter. It typically had two distributing units, each with seed hopper, meter, tube, and shoe-type furrow opener (to maintain a straight row), and a concave steel presswheel, mounted on a three-wheel sulky frame. At the side, a marker, usually a disk on an extended rod,

assisted by indicating the center of the next set of rows. With changes in the seed metering device, the planters could be adapted to most row crops. A more ingenious variant, the checkrow planter, seeded with such accuracy that the cross-rows were straight. As this planter traveled down the rows, a check reel on the planted side gathered in a wire anchored at the row's end and a reel on the unplanted side dispensed wire for the next pass. Uniformly-spaced buttons on the wire caused the seed valve in each dispensing mechanism to trip, planting hills of seeds at even intervals. This method was commonly used in the Corn Belt, as cotton and other row crops were usually drilled with little regard for the spacing between the seeds until the late 1940s. Cross-cultivating was the principal advantage of a checkrow planting. Farmers hoping to reduce spring thinning had to wait for the development of precision planters. These machines, introduced in the post-WWII era, placed single seeds at uniform intervals to form a stand that could be thinned entirely by machine or with only a minimum of hand hoeing. The planters relied on two new elements. The first was a highly accurate seed-metering device, added to the traditional row crop drill. The second, and far more important, was seed processed to be uniform in size and shape, which would germinate at a high rate.

Cultivators include implements used to loosen and pulverize the soil but without inverting it as in plowing. Jethro Tull, the eighteenth-century English pioneer of agricultural technology, is credited with first attempting to replace hand hoeing in these tasks with horsepower. The primary purpose was to destroy weeds. Besides promoting plant growth through killing weeds, cultivation (or tillage performed after the crop is planted) also may aid in the application of irrigation water, incorporate chemical fertilizers, and facilitate the harvest.

The slave South plantation owners were slower to adopt mechanical technologies in cotton production, but even here one sees labor-saving advances that reduced the need for hoeing. Examples include the use of equipment for shallow cultivation, such as scrapers, skimmers, and sweeps. By some accounts, the scraper, which could shave the bed close to the cotton, cut the labor needed to clean and thin an acre in half. Many planters also adopted mechanical seeders, which saved labor at seeding time. The trend was to plant less seed more carefully to cut the time needed to thin and cultivate the crop (Gray, 1941, pp. 700–702).

Cotton Mechanization: Gins and Harvesters

The two big breakthroughs in the mechanization of cotton production were separated by roughly 150 years. In 1790, cotton was a relatively minor crop in the fledgling US; long-staple Sea Island cotton had only recently been brought to the US; the low quality short-staple Upland varieties of the day were mostly grown for home consumption. By 1850, cotton was the nation's leading export crop, and the US dominated the world cotton market. Cotton became by far the South's leading crop and the most important use of slave labor. The usual story explaining this transition combines the increased world demand stemming from the Industrial Revolution in Britain and the genius of Eli Whitney, who, in 1793, invented the saw-toothed cotton gin (which removed the seeds from the lint). Soon after that, models allowed one laborer to do the work of a 100 workers plucking the seeds by hand. Improved versions were much more productive. Table 2 traces the number pounds of cotton cleaned per day using various techniques. Whitney's gin broke a technological bottleneck allowing southern planters to vastly expand cotton production. The cotton gin represents an example par excellence of a labor-saving innovation.

Table 2 Cotton ginned per day

Method	*Quantity (£)*
Hand (1788)	2
Whitney (1793 Saw Gin)	80
Whitney (1800 Model)	350
Improved (1866 Gin)	3000

Source: Compiled from Lebergott, S., 1984. The Americans. New York: W.W. Norton, p. 170.

The story usually ends here, but much more needs telling. First, recent research suggests that adapting more primitive roller gins, which had long been available, might have at least partially solved the ginning problem. Such gins were capable of separating 25 pounds per work-day of Sea Island cotton. In additions, inventors besides Whitney were developing saw gins for upland cotton. So Whitney's invention was important, but perhaps not absolutely necessary. Secondly, and paradoxically, over the long run the gin led the South to require more not less labor: the labor-saving gin made growing labor-using cotton profitable. Before its invention, the high labor requirement made cotton uncompetitive with grain in labor-scarce America. After the Whitney's invention cut the ginning requirements, cotton crossed the threshold of profitability and was cultivated on an extensive scale. Finally, although the gin was important, another truly critical factor propelling the growth of the South's cotton industry in the pre-Civil War era was the work of plant breeders who produced higher quality varieties that were also far easier to pick, more productive, and more disease resistant. Largely because of better varieties, the quantity of cotton a slave could pick in a day increased about four times between 1810 and 1860. So, the final assessment is that invention, refinement, and spread of Whitney's gin represented a key mechanical innovation in the development of agriculture, but there was a lot else going on (Olmstead and Rhode, 2008b; Lakwete, 2003, pp. 22–23).

A number of mechanical innovations increased productivity in cotton production, but the next truly revolutionary advance did not begin to diffuse until after WWII. In 1928, J. D. Rust perfected a primitive spindle machine, but the depression era labor glut limited demand for this innovation and discouraged investors. When labor became scarce during and after WWII, the machine still needed to be perfected to be suitable for wide adoption. In addition, cotton breeders needed to create a less woody plant that ripened uniformly to make machine picking more feasible. In an earlier age, breeders had worked to make 'high' cotton that ripened in stages to make hand pickers more productive; now they

changed course to meet the needs of the new machines. Both private and government breeders undertook this challenge.

At this juncture, California once again took center stage in the history of the cotton picker much as it did in the development of the combined harvester. Cotton did not emerge as a significant crop in California until WWI. In fact, despite many attempts to introduce cotton dating back to the Mission era, continuous production on even a small scale did not begin until 1906. In terms of bales produced California ranked tenth among all states in 1929. By 1959, it ranked second. Many of the same economic and geographical conditions (high wages, large farms, dry weather during the harvest, etc.) that made California farmers eager adopter of combined harvesters also applied to cotton harvesters. Picker manufactures understood this and focused their early experiments and first commercial ventures in the San Joaquin Valley. In 1943, International Harvester evidently had five one-row pickers operating commercially in the valley. These were experimental machines which would need improvement. In addition, Mack Rust (J. D.'s brother) moved to California to test and perfect his machine. Gradually the mechanical defects were worked out and the Rust machine became commercially viable in the late 1940s. Allis Chalmers and Ben Pearson, Inc. both began making the Rust machines under license in 1949. The number of machines thought to be working in California increased from 20 in 1945 to 3700 in 1951 – this represented 50% of the machines in the US. In 1955, machines harvested approximately 65% of California's cotton compared to approximately 25% for the nation as a whole. By 1970, virtually the entire US cotton crop was mechanically harvested. The mechanization of the cotton harvest, coupled with the decline in cotton acreage, were among several factors that contributed to the contraction of the southern labor market as the number of sharecroppers fell from 776 000 in 1930 to 121 000 in 1959 (Street, 1957; Musoke and Olmstead, 1982).

Dairy Innovations: From Churns to Milking Machines

There is an old saying that "farming ain't what it used to be." Few farming sectors have changed as much as dairying. New technologies changed the gender division of labor, increased productivity, changed the physical location of many activities from farms to creameries, led to significantly lower consumer prices, and vastly increased food safety. Dairy farming was historically a highly labor intensive activity. The rise of commercial dairying in the early nineteenth century created economic opportunities, particularly for women, who provided almost all of the labor for milking cows and making butter and cheese. Dairying ranked with nascent textile manufacturing sector as a source of employment for northern women in the mid-nineteenth century. As milk output increased and cow lactation periods lengthened because of better breeds and feeding methods, dairying provided more year-round employment. Making butter was arduous. After milking the cows, women carried the milk to the milkhouse, poured it into skimming pans, skimmed the cream, churned it into butter, drained out the buttermilk and kneaded in salt, packed the butter into molds to form bricks, and then packed the bricks into pails or boxes (Jensen, 1986, pp. 92–113).

There was a stream of labor-saving mechanical innovations in butter production, many aimed at producing a better churn. From 1802 to 1849, the Office of Patents issued nearly 250 patents on butter making machinery, 86% of them for churns. The new technologies had an enormous impact. During the colonial period women often churned butter using a bowl and spoon. Dasher churns were common in some areas by the 1770s. With this device a women could make one or two pounds of butter at a time; this achievement required working the churn for approximately 3 h. Although still laborious, this was a significant improvement over using a spoon and bowl. By 1850, improved churns produced approximately 125 lb of butter in as little as 90 min. The larger churns were powered by dogs, sheep, or calves walking on a treadmill. The advent of the creamery moved butter and cheese production off the farm and changed the gender division of labor by bringing more men into the activity (Jensen, 1988, p. 820; 1986, pp. 104–105).

The movement of cheese and butter making to the factory allowed for more economies of scale, and creameries adopted a number of biological and mechanical innovations. The continuous centrifugal cream separator invented by Carl Gustav Patrik De Laval of Sweden in 1878 was particularly significant. American inventors were also at work – between 1872 and 1909, the US Patent Office issued 127 patents for milking machines. The early De Laval machines could process approximately 300 lb of milk a day. This was an enormous advance over letting gravity separate the cream in shallow pans for 2–3 days (during which milk often soured). Danish immigrants brought the first separator to the US in 1882 (Christensen, 1939, p. 338; Edwards, 1949; Jensen, 1986, pp. 98–9; Fussell, 1966, pp. 160–202).

By the twentieth century, many of the mechanized activities had moved off the farm. The functions the remained on farms ensured that dairying remained a highly labor-intensive activity. Ca. 1910, a dairy farmer had to work 10 times as many hours as a modern farmer to produce one gallon of milk. Ca. 1940, dairying (including the caring for dairy animals) required almost 4 billion hours of labor per year in the US; this was one-and-a-half times more than that devoted to producing cotton. One of the most important mechanical developments was the milking machine employing the intermittent suction principle. First marketed approximately 1905, these machines saved approximately 30 h per cow, or about one-fifth of the annual labor requirement. The machines spread slowly at first, owing to the structure of dairy farming, the lack of electricity, improper sanitary practices, and 'hard times' on the farm. In 1910, approximately 12 000 farms possessed milking machines; this was less than one of every 400 farms that reported dairy cows. By 1940, the number of farms possessing milking machines had climbed to 190 000. But at even at this date, about only one in ten dairy cows was milked by machine. Thereafter, diffusion was rapid, with one-half of cows milked mechanically by 1950. By 1965, approximately 500 000 farms, including virtually all commercial dairies, reported using milking machines. The spread of milking machines was part of a larger mechanical revolution on dairy farms; other changes included refrigeration, electric lights, and improved hay harvesting and manure handling machinery, and transportation equipment. Bulk cooling and

handling techniques made the traditional milk can obsolete (Forste and Frick, 1979).

Perspectives

To this juncture, our story has emphasized the role of mechanization in reshaping the productivity and structure of American agriculture. Other forces arising from better and more intensive applications of chemistry, biology, and genetics to agriculture have also played a major role. Social scientists long argued that in the US relatively cheap land and expensive labor led farmers, inventors, firms, and governments to concentrate on mechanization rather than other forms of technical change (which for simplicity the authors have called 'biological innovations'). By this reasoning, biological innovations such as hybrid corn only became prominent after the 1930s – well after the closing of the frontier and when, according to the standard account, an increasing scarcity of land and a rapid decline in commercial fertilizer prices made such innovations profitable. Proponents of this view explicitly argued that mechanical technologies were almost exclusively labor saving – they increased the output per worker. Biological technologies were primarily land saving – they increased output per acre (Cochrane, 1979, pp. 201–202). This stylization seemed to fit the long sweep of American development, because until the 1930s output per worker had risen considerably, but output per acre for major crops had changed little. Although still repeated, this general view has recently been discredited.

For many reasons, trends in output per acre understate the contributions of biological innovations. Agricultural production is an inherently biological process that uses organisms to transform sunlight and soil nutrients into food and fiber. Evolving pests and diseases constantly threaten the efficiency of this transformation process. Machines may become obsolete, and they can wear out; but a new machine of the outdated design will work more or less like the equipment it replaced. This is not true for biological technologies. Farmers and scientists have long understood the Red Queen effect: one has to run fast just to stay in one spot. A once productive plant variety can become worthless as pathogens evolve to penetrate its defenses. Moreover, the introduction of invasive species from foreign lands can dramatically cut yields. In addition, yields often suffered as agriculture moved westward. Introducing production to new environments required biological learning that involved adapting plants to meet new, often hostile, conditions.

The once strict association of machines with only saving labor and of biological advances with only saving land is very questionable. As noted above, the tractor 'saved' over 160 million acres of crop and pastureland by the 1940s, and better cotton varieties increased slave picking productivity by four times in the half century before the Civil War. These are not isolated examples. What sense does it make to say that better tillage equipment are machines so they save labor, but if a farmer replaces some of this equipment with improved herbicides, this saves land? Once one abandons the old paradigm and reexamines American agricultural development, a record of biological innovation emerges that went hand in hand with the better documented record of mechanization. New wheat varieties allowed for movement of production onto colder, hotter, and more arid lands. New varieties also were constantly introduced and developed to combat rusts and other diseases. New corn varieties merged the old northern flints with southern dents to produce the prolific varieties that would define the American Corn Belt. Researchers then set their sights on pushing production into colder climates. Soybeans, alfalfa, and Bahia oranges, and numerous other plants were introduced and acclimated for varied growing conditions. Breeders redesigned the structure of all major species of livestock, vastly increasing their productivity. Often, biological and mechanical innovations depended on one another, as with the breeding cotton and tomato varieties more suitable for machine picking. In 1920, the vast majority of the plows, reapers, and combines operating in American wheat fields worked land that had not been in agricultural production in 1850; and, given the wheat varieties known in America at that earlier date, land which could not have sustained commercial wheat production. The key point is that America's long history of agricultural mechanization was a part of a much more dynamic set of events (Olmstead and Rhode, 2008a). Together, mechanical and biological innovations fundamentally restructured rural America, and vastly increased the supplies of food and fiber for a demanding world.

Glossary

Common agricultural policy instruments That alter international competitiveness include both border and domestic measures. Border measures include import and export taxes and subsidies, as well as quantitative restrictions such as import or export quotas or bans. All of these measures drive a wedge between the prices observed in domestic and international markets. This wedge has the same magnitude for producers and consumers at least at the border, in contrast to price-distorting domestic consumer and producer taxes or subsidies or quantitative restrictions on consumption or production, which affect just one of those two sides of the market for internationally tradable goods. Domestic subsidies or taxes on or border measures affecting inputs into farming also will alter producer incentives and, in the process, distort the demand for and prices of inputs. These contrast with government-provided or government-subsidized investments in agricultural R&D, rural infrastructure, or rural education and health, which can increase returns to producers without directly distorting product or input prices.

The nominal rate of assistance (NRA) Measures market distortions imposed by governments that create a gap between the current domestic price of a product and the price that would exist under free markets. Under the 'small-country' assumption, this rate is computed as the percentage by which government policies have raised gross returns to farmers above what they would have been had the government not intervened (or the percentage by which government policies have lowered gross returns, if NRA <0). It therefore includes the effect of not only output-price-distorting policy instruments but also measures that alter the cost of farm inputs.

The relative rate of assistance (RRA) Is defined in percentage terms as:

$$\mathrm{RRA} = 100 * [(100 + \mathrm{NRAag}^{t})/(100 + \mathrm{NRAnonag}^{t}) - 1]$$

where NRAag^{t} and $\mathrm{NRAnonag}^{t}$ are the percentage NRAs for the tradable parts of the agricultural and nonagricultural sectors, respectively. If both of these sectors are equally assisted, the RRA is zero. This measure is useful in providing an internationally comparable indication of the extent to which a country's sectoral policy regime has an anti (or pro-) agricultural bias. The RRA recognizes that farmers are affected not just by prices of their own products and inputs but also by the incentives faced by nonagricultural producers bidding for the same mobile resources.

The trade reduction index (TRI) Measures the extent to which import protection or export taxation reduces the volume of trade. The TRI is defined as the percentage uniform trade tax that, if applied equally to all agricultural tradables, would generate the same reduction in trade volume as the actual intrasectoral structure of distortions to domestic prices of such tradable goods.

The welfare reduction index (WRI) Is the percentage uniform trade tax that, if applied equally to all agricultural tradables, would generate the same reduction in national economic welfare as the actual intrasectoral structure of distortions to domestic prices of these tradable goods. The WRI recognizes that the welfare cost of a price distortion imposed by a government is related to the square of the price wedge and thus is positive, regardless of whether the government's policy favors or hurts producers in a particular sector.

Introduction

Throughout history the agricultural and food sector has been subjected to perhaps more heavy-handed governmental interventions than any other sector. Agricultural trade-related policies account for an estimated 70% of the global welfare cost of all merchandise trade distortions, even though the agricultural sector contributes only 6% of global trade and 3% of global income (Anderson *et al.*, 2010, Table 2.3).

For advanced economies, the most commonly articulated reason to restrict food trade has been to protect domestic producers from import competition as they come under competitive pressure to shed labor. Such measures harm not only domestic consumers and exporters of other products but also foreign producers and traders of food products. For decades, agricultural protection and subsidies in high-income (and some middle-income) countries have depressed international prices of farm products, lowering the earnings of farmers and associated rural businesses in developing countries.

Meanwhile, developing countries' policies have further depressed the price incentives for their farmers, thus exacerbating the deleterious effects of the richer countries' farm policies. Governments of many developing countries have taxed their farmers more heavily than producers in other sectors. In addition, many developing countries chose to overvalue their currency and to pursue an import-substituting industrialization strategy by restricting imports of manufactures. Together, these measures have indirectly taxed producers of other tradable products in developing economies, most of whom have been farmers.

The resulting disarray in world agriculture has manifested itself in overproduction of agricultural products in high-income countries and underproduction in low-income countries. This disarray also means that there has been less international trade in such products than would have been the case under free trade. The end result is thinner and thus more volatile markets for these weather-dependent products.

Agricultural policies became newsworthy during 2008–12 because international food prices spiked upwards three times in that period. Biofuel policies have partly caused these price spikes, and in turn, the effects of biofuel policies have been exacerbated by the trade-policy responses of numerous countries at a time of low global grain stocks. Responses by food-surplus developing countries have typically involved restrictions on exports, while those by food-deficit developing countries have involved a lowering of import barriers. The ostensible motivation of policymakers has been to prevent a decline in national food security: each country has aimed to protect its domestic consumers (and indirectly, to protect the current government from losing power). Together, however, these measures have amplified international price spikes so that each country's measures have harmed other countries' consumers (Carter *et al.*, 2011; Martin and Anderson, 2012).

Changes in food prices create winners and losers, especially among the poor. It has been argued for decades that such distortions have added to global inequality and poverty, because three-quarters of the world's poorest people depend, directly or indirectly, on agriculture as their major source of income (World Bank, 2007). Protectionist policies of high-income countries have been partly responsible for international income inequality and poverty in developing countries, but so too has the antiagricultural bias of many developing countries' policies, according to a recent set of economy-wide empirical studies (Anderson *et al.*, 2010).

The agricultural policies of rich countries have not been motivated by their effects on global poverty but rather by domestic political concerns. Agricultural policy remains important in rich countries despite the relatively small and still-declining share of agriculture in GDP and employment. For example, the common agricultural policy (CAP) in the European Union (EU) continues to absorb 40% of the entire EU budget. That importance is reflected in the priority these countries' trade negotiations place on farm policies in the current round of World Trade Organization (WTO) negotiations – on which the future growth of global income and the trade of all goods and services depend.

Some agricultural- and trade-policy developments of the past half-century have happened quite suddenly and been transformational. Such events include decolonization in Africa and elsewhere around 1960; the creation of the CAP in Europe in 1962; the introduction of flexible exchange rates from the 1970s; liberalization, deregulation, privatization, and democratization in many countries from the mid-1980s; the opening of markets in China in 1979, in Vietnam in 1986, and in Eastern Europe (following the fall of the Berlin Wall) in 1989; and the demise of the Soviet Union in 1991. However, less well known are the influences of policies that change gradually in the course of economic development, as incomes grow and comparative advantages evolve. Even these patterns are subject to disruption though: since the 1980s many countries have begun to reform their agricultural and trade policies. These trends and turning points are revealed in a global five-decade database of evidence recently compiled by the World Bank, exposing the extent to which recent agricultural policy reforms have succeeded in reversing the prior era's policy distortions – and throwing up signs of an emergence of agricultural protection in middle-income countries (see Section Policy Impacts on Agricultural Prices). Recent improvements in political-economic conceptual lenses, combined with this global database, allow the empirical testing of a rich menu of hypotheses about patterns of market intervention across countries, commodities, and policy instruments (see Section Why Governments Distort Agricultural Markets the Way They Do?). This in turn provides insights into the sustainability of these reforms (see Section Prospects for Further Policy Reforms).

Policy Impacts on Agricultural Prices

Empirical indicators of agricultural price distortions have been provided annually since the late 1980s by the Secretariat of the Organisation for Economic Co-operation and Development (OECD) (2012) for its 30-member countries. They have become known as producer and consumer support estimates, or PSEs and CSEs. The Organization for Economic Co-operation and Development (OECD) (2009) has also released PSEs and CSEs for Brazil, China, South Africa, and former Eastern bloc countries, which are being updated bi-annually. However, the OECD provides no comprehensive time-series rates of assistance to producers of nonagricultural goods to compare with the PSEs, or of what took place in those advanced economies during earlier decades. Data for these earlier decades from today's developed economies are needed in order to assess how various countries' policies evolved during stages of development similar to those of today's middle-income countries. As for developing countries, almost no comparable time-series estimates were generated in the two decades following the seminal work of Krueger *et al.* (1988, 1991), which covered between 15 and 25 years before 1985, until the release in 2008 of a new database of agricultural distortions by the World Bank (Anderson and Valenzuela, 2008, updated and extended by Anderson and Nelgen, 2013). This new data set complements and extends the OECD's PSE/CSEs and the Krueger, Schiff, and Valdés studies. It provides similar estimates for significant developing economies, and it estimates new and more comprehensive policy indicators.

The new World Bank database covers 82 countries that together account for between 90% and 96% of the world's population, farmers, agricultural GDP, and total GDP. The sample countries also account for more than 85% of agricultural production and employment in each of Africa, Asia, Latin America, and the transition-economies region of Europe and Central Asia, as well as for all of agricultural production and farm employment in OECD countries. Not all countries had annual data for the entire 1955–2010 period, but the average number of years covered is 45 per country. Policy indicators are computed for 75 different farm products, with an average of almost 11 per country. This product coverage represents approximately 70% of the gross value of agricultural

production in each of the focus countries and just under two-thirds of global agricultural production, valued at undistorted prices over the period covered. Of the world's 30 most valuable agricultural products, the indicators cover 77% of global output (ranging from two-thirds for livestock to three-quarters for oilseeds and tropical crops and five-sixths for grains and tubers). These products represent 85% of global agricultural exports. Such comprehensive coverage of countries, products, and years offers a reliable picture of long-term trends and fluctuations in policy indicators for individual countries and commodities, as well as for country-groups, regions, and the world as a whole. This data set reveals distinct patterns of price distortions across countries and over time, as well as policy turning points. After defining the indicators, these patterns are summarized here under four headings: sectoral distortion variation across countries; intrasectoral variation across farm products; year-to-year variations in rates of distortion; and policy-instrument choices.

Measures of Price Distortions

Typically, agricultural and nonagricultural trade measures (border taxes and protectionist nontariff barriers (NTBs)), together with multiple exchange rates, have distorted product prices more commonly than have trade subsidies, direct domestic producer or consumer subsidies, or domestic taxes or quotas that alter product or input prices. However, in high-income countries, export subsidies grew in importance in the 1970s and 1980s and, since the 1980s, domestic support measures that (to varying extents) are decoupled from production decisions have begun to play a larger role. Furthermore, since the inception of the WTO in 1995, most NTBs have been converted to tariffs. In many countries, however, those tariffs have been legally bound at well above applied rates, and are specific to the quantity imported rather than a percentage of the import price, so that such countries have been able to continue to vary the extent of their border restrictions as international prices or domestic supplies fluctuate from year to year.

To capture the extent of government intervention on farmer incentives, a nominal rate of assistance (NRA) is estimated. The NRA measures distortions imposed by governments that create a gap between current domestic price and the price that would exist under free markets. Under the 'small-country' assumption, this rate has been computed for each product as the percentage by which government policies have raised gross returns to farmers above what they would have been had the government not intervened (or the percentage by which government policies have lowered gross returns, if NRA < 0). The rate includes the output-price-altering equivalent of any product-specific input subsidies or taxes. (The NRA differs from the OECD's PSE in that the PSE is expressed as a percentage of the distorted rather than the undistorted price, and hence is typically smaller than the NRA and cannot exceed 100%.)

A weighted-average NRA for all available products is derived using the value of production at undistorted prices as product weight. To this NRA for available (covered) products is added a 'guesstimate' of the NRA for noncovered products (on average, approximately 30% of the total in value terms), along with an estimate of the NRA from nonproduct-specific forms of assistance to (or taxation of) farmers.

Since the 1980s, some high-income governments have also provided decoupled assistance to farmers. Because this support, in principle, does not distort resource allocation, its NRA has been computed separately and is not included for comparison with the NRAs for other sectors or for agriculture in developing countries. Each year, each covered commodity's industry is classified as either import-competing, as producing an exportable, or as producing a nontradable. The aggregate noncovered industry group is also subdivided into these three categories. This classification allows the generation each year of the weighted-average NRAs for exporting versus import-competing producers to capture changes in the antitrade bias that typically prevails.

Also reported is a production-weighted average NRA for nonagricultural tradables, so that this rate may be compared to the rate for agricultural tradables via the calculation of a relative rate of assistance (RRA). The RRA recognizes that farmers are affected not just by prices of their own products but also by the incentives faced by nonagricultural producers bidding for the same mobile resources. That is, it is relative prices, and hence relative rates of government assistance, that affect incentives to producers. The RRA is defined in percentage terms as:

$$\mathrm{RRA} = 100 * [(100 + \mathrm{NRAag}^{t})/(100 + \mathrm{NRAnonag}^{t}) - 1]$$

where NRAag^{t} and $\mathrm{NRAnonag}^{t}$ are the percentage NRAs for the tradable parts of the agricultural (including noncovered) and nonagricultural sectors, respectively (Anderson *et al.*, 2008). Note that if both of these sectors are equally assisted, the RRA is zero. This measure is useful because, if it is below (or above) zero, it provides an internationally comparable indication of the extent to which a country's sectoral policy regime has an anti- (or pro-) agricultural bias.

The cost of government policy distortions in terms of resource misallocation tends to be greater as the degree of substitution in production increases. In the case of agriculture, which involves the use of land that is sector-specific but transferrable among farm activities, the greater the dispersion of NRAs across industries within the sector, the higher will be the welfare cost of those market interventions. For this reason it is also useful to draw on indicators developed by Anderson and Neary (2005) and adapted for agriculture by Lloyd *et al.* (2010). These are a welfare reduction index (WRI) and a trade reduction index (TRI). The former measure recognizes that the welfare cost of a price distortion imposed by a government is related to the square of the price wedge and is thus positive, regardless of whether the government's policy favors or hurts producers in a particular sector. The TRI measures the extent to which import protection or export taxation reduces the volume of trade. It is the percentage uniform trade tax that, if applied equally to all agricultural tradables, would generate the same reduction in trade volume as the actual intrasectoral structure of distortions to domestic prices of such tradable goods. Similarly, the WRI is the percentage uniform trade tax that, if applied equally to all agricultural tradables, would generate the same reduction in national economic welfare as

the actual intrasectoral structure of distortions to domestic prices of these tradable goods.

Variations in Sectoral Distortions

Historically, the higher a country's per capita income, the higher have tended to be its nominal – and especially relative – rates of assistance to agriculture (NRAs and RRAs). More generally, policy regimes, on average, have had a pro-agricultural bias in high-income countries and an anti-agricultural bias in developing countries. However, since the 1980s, both the antiagricultural policy bias in developing countries and the pro-agricultural bias in high-income countries have diminished, and the two groups' average RRAs have converged toward zero (Figures 1 and 2).

In the case of developing countries, it is clear from Figure 2(a) that the rise in their average RRA is due as much to a decline in assistance to nonfarm sectors (especially cuts to manufacturing protection) as to declines in agricultural disincentives (especially cuts to export taxes). However, the extent and speed of convergence vary across regions. Among developing countries, convergence has been greatest for Asia and least for Africa; among high-income countries, it has been greatest for the EU and almost nonexistent for other Western European countries. The sole exception is the dip for most countries in 2005–10, when international food prices rose steeply. For EU members, the RRA declined from an average of 77% in the 1980s to 11% in 2005–10. Consequently, the trade- and welfare-reduction indexes of the two main country-groups have traced an inverted-U shape, rising in the mid-1980s before more than halving since then (Figure 3).

The averages reported in Figures 1–3 hide the fact that both the level and rate of change in distortion indicators still vary considerably across countries. National RRA estimates for 2005–09 varied from approximately 40% for several African countries to approximately 100% for a few high-income countries (Figure 4). Clearly, much could be gained from further reforms to remove these cross-country differences, which would lead to international relocations of production and consumption.

The extent to which RRAs vary at any level of per capita income or comparative advantage is substantial. Based on regression analysis over the full time series from 1955 to 2007, per capita income and comparative advantage account for 59% of the variation in RRAs globally. Note that the average RRA for developing countries, which converged toward zero from the 1980s, did not stop at zero but 'overshot.' For Korea and Taiwan, this evolution to a positive RRA occurred in the early 1970s, for the Philippines it happened in the latter 1980s, and for China, India, Indonesia, and Malaysia it happened in the first decade of the current century. By just focusing on agricultural NRAs, and bearing in mind the sharp rise in international prices of farm products in 2008, it is clear from Figure 5 that agricultural protection is growing in Asia's three most populous countries.

Intrasectoral Distortion Variations

Within a country's agricultural sector, whether the country is developed or developing, product NRAs vary widely (Figure 6). Some commodity product NRAs are positive and high in almost all countries (sugar, rice, and milk). Others are

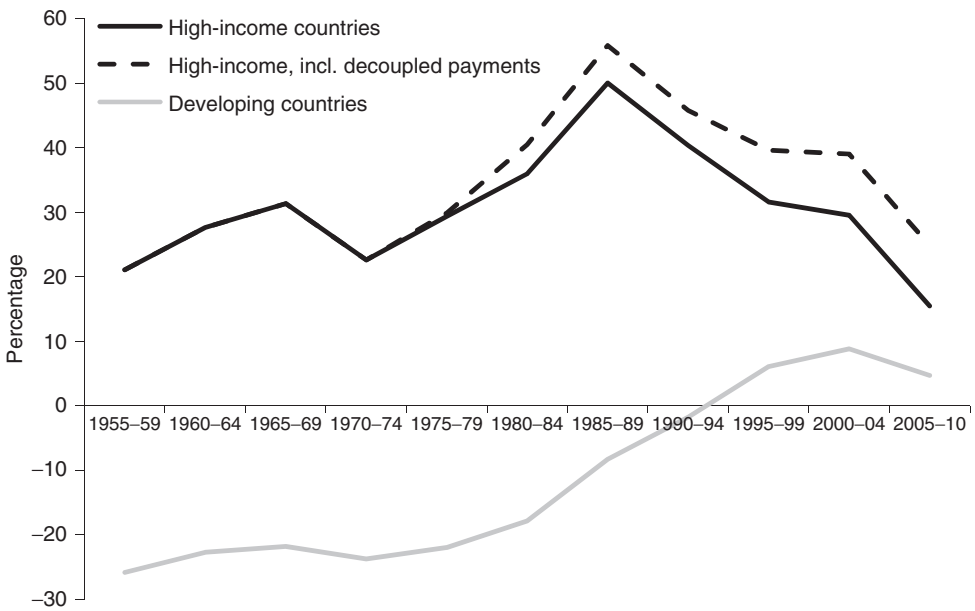

Figure 1 Nominal rates of assistance to agriculture in high-income and developing countries, 1955–2010 (%). Five-year weighted averages, with decoupled payments included in the dashed line. Figure 2 Developing and high-income countries' nominal rates of assistance (NRAs) to agricultural and nonagricultural tradable sectors, and relative rates of assistance (RRAs), 1955–2010 (%). Calculations use farm production-weighted averages across countries. RRA is defined as $RRA = 100 * [(100 + NRAag^t)/(100 + NRAnonag^t) - 1]$, where $NRAag^t$ and $NRAnonag^t$, respectively, are the percentage NRAs for the tradable segments of the agricultural and nonagricultural sectors. Reproduced from Anderson, K. (Ed.), 2009. Distortions to Agricultural Incentives: A Global Perspective, 1955–2007. London: Palgrave Macmillan and Washington, DC: World Bank (Chapter 1), updated from estimates in Anderson, K., Nelgen, S., 2013. Updated National and Global Estimates of Distortions to Agricultural Incentives, 1955 to 2011. Available at: www.worldbank.org/agdistortions (accessed 29.04.14).

positive and high in developed economies but have been highly negative in numerous developing countries (most noticeably, cotton). Still other product NRAs are relatively low in all countries (feed grains and soybeans as inputs into intensive livestock; pork and poultry as standard-technology industrial activities).

The failure of global variability across commodities to decrease significantly suggests that the movement of the

Review of Development Economics 14 (2), 141–160, based on time-series estimates in Anderson, K., Croser, J.L., 2009. National and Global Agricultural Trade and Welfare Reduction Indexes, 1955 to 2007. Available at: www.worldbank.org/agdistortions (accessed 29.04.14), and updated using Anderson, K., Nelgen, S., 2013. Updated National and Global Estimates of Distortions to Agricultural Incentives, 1955 to 2011. Available at: www.worldbank.org/agdistortions (accessed 29.04.14).

mean-NRA toward zero has not been accompanied by a fall in the variance across commodities within the sector. This pattern explains why the WRI in Figure 3(b) is still well above zero, because the welfare cost of a sector's policy regime is greater the more dispersed are commodity NRAs within that sector. As is the case for variations in sectoral distortion across countries, much could be gained from intra-country resource reallocation within the agricultural sector and from the altered consumption patterns that would emerge from removing cross-product differences in NRAs.

A crucial component of the NRAs' product dispersion is that the agricultural policy regimes across countries tend to have an antitrade bias. This bias has declined over time for the developing-country group, mainly owing to declines in agricultural-export taxation, and despite growing agricultural-import protection. For the high-income group, the anti-agricultural trade bias has shown less of a downward trend over time, because agricultural-export subsidies rose and then declined, as did import protection (Figure 7). These factors explain the smaller decline in the TRI for high-income versus developing countries (Figure 3(a)).

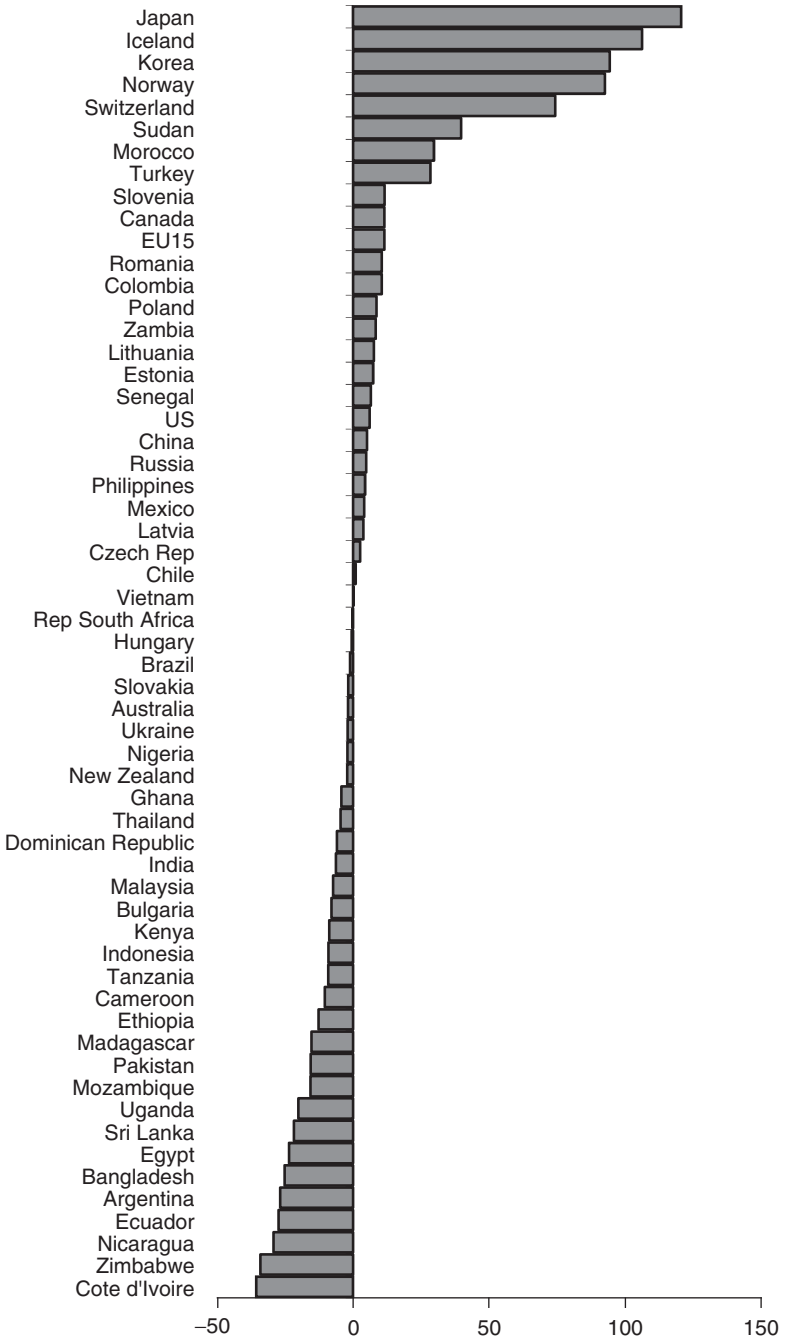

Figure 4 Relative rates of assistance by country, 2005–10. Reproduced from Anderson, K. (Ed.), 2009. Distortions to Agricultural Incentives: A Global Perspective, 1955–2007. Year-to-Year Variation

Around the long-run trend for each country, much fluctuation is seen from year to year in individual product NRAs. This tendency has not diminished since the mid-1980s for developing countries, and it has even increased for high-income countries. The negative correlation of a commodity's NRA with movements in its international price is largely responsible for this pattern. On average, barely half of the change in an international price is transmitted to domestic markets within the first year. As noted in the Section Introduction, governments are keen to prevent domestic prices from being affected by spikes in international prices. In both agricultural-exporting and agricultural-importing countries, and in high-income as well as developing countries, large changes in NRAs occur during periods of international price spikes – whether up, as in 1974 and 2008, or down, as in 1986 (Anderson and Nelgen, 2012).

Relative Contributions of Policy Instruments

Across countries and time periods, governments have used a broad array of policy instruments. These include distortions to input markets (largely subsidies, plus controls on land use), production quotas, marketing quotas, target prices, price subsidies or taxes in output markets, and, especially, border measures that directly tax, subsidize, or quantitatively restrict international trade. Meanwhile, public agricultural-research investments amount to less than 2% of the gross value of agricultural output at undistorted prices in high-income countries. In developing countries, an even smaller percentage (1%) has been devoted to research and development (Anderson, 2009, Table 1.11).

Country expenditures on public-good research investments pale in comparison to losses resulting from commodity price distortions. The major vehicles responsible for these losses are trade-policy instruments such as export and import taxes and subsidies or quantitative restrictions, along with (in the past) multiple exchange rates. These trade-policy instruments account for no less than three-fifths of agricultural NRAs globally. As a result, they are responsible for an even larger share of the global welfare cost and agricultural WRIs, because trade measures also tax consumers, and welfare costs are proportional to the square of a trade tax. In contrast, internal domestic agricultural policies that directly subsidize or tax outputs and inputs have contributed only minimally to NRAs in the past.

Among trade-distorting policy instruments, it is clear from Figure 8 the extent to which export taxes have been phased out by developing countries. In sharp contrast, as assistance to import-competing agricultural subsectors of developing countries has grown (Figure 7(a)), the relative importance (from a national welfare perspective) of import taxes has increased dramatically (Figure 8). In Western Europe, the growth of decoupled, more direct income-support measures, along with the virtual abolition of all support measures in Australia and New Zealand, reveals a far different pattern than in high-income countries in East Asia, where border-measure supports continue to dominate (Figure 9).

Input subsidies are a relatively minor component of most countries' assistance to farmers. But they lingered on in Australia and New Zealand when most other forms of assistance were being phased out, and such subsidies have also remained approximately one-fifth of the total NRA in the US (Anderson, 2009, Chapters 4 and 5). With two notable exceptions, input subsidies are even less common in developing countries, where funds for such direct subsidies are scarcer. The important exceptions are India and Indonesia. In India, input

Five-year weighted averages for covered products only. The total also includes nontradables. The straight line in the upper segment of each graph represents an ordinary-least-squares regression based on annual NRA estimates. Reproduced from Anderson, K. (Ed.), 2009. Distortions to Agricultural Incentives: A Global Perspective, 1955–2007. London: Palgrave Macmillan and Washington, DC: World Bank (Chapter 1), updated using Anderson, K., Nelgen, S., 2013. Updated National and Global Estimates of Distortions to Agricultural Incentives, 1955 to 2011. Available at: www.worldbank.org/agdistortions (accessed 29.04.14).

subsidies contributed 7–9% points to the agricultural NRA in the 1990s and 10 points in 2000–04. In Indonesia, such subsidies have contributed 2–4% points to the agricultural NRA since 1990. They also contributed from 5 to 9 points in the 1970s and 1980s, even at times when the overall agricultural sector of these countries had a negative NRA.

Up to the 1980s – and in some cases the early 1990s – it was quite common for developing-country governments to intervene in the market for foreign exchange. Such interventions added to the antitrade biases that were targeted at tradable sectors, including agriculture. However, these interventions largely disappeared by the mid-1990s, as initiatives took hold to reform overall macroeconomic policy. In China, for example, trade taxation associated with the country's dual- exchange rate system accounted for almost one-fifth of the (negative) RRA in the 1980s. However, since the mid-1990s, that system has been abolished (Huang *et al.*, 2009).

As governments seek to prevent domestic prices from being affected by periodic spikes in international prices, large

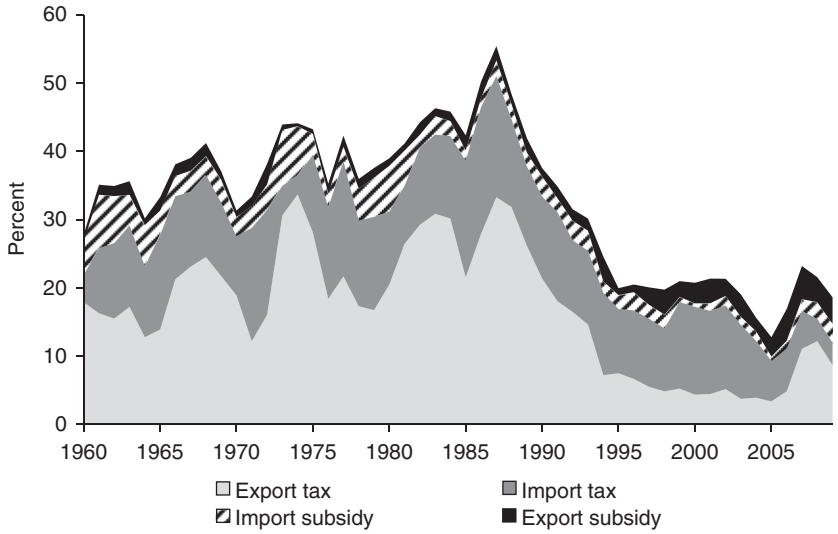

Figure 8 Contributions of various instruments to the border component of the welfare reduction index (WRI) for developing countries, 1960–2010 (%). Derived from estimates reported in Croser, J.L., Anderson, K., 2011. Changing contributions of different agricultural policy instruments to global reductions in trade and welfare. World Trade Review 10 (3), 297–323, updated using Anderson, K., Nelgen, S., 2013. Updated National and Global Estimates of Distortions to Agricultural Incentives, 1955 to 2011. Available at: www.worldbank.org/agdistortions (accessed 29.04.14).

changes in the relative importance of different policy instruments occur. This is evident from the estimated contributions to total agricultural WRIs of various policy instruments during the upward price spikes around 1974 and 2008 and the downward spike around 1986 (Figure 8). In some cases, trade taxes even temporarily disappeared; in other cases, trade subsidies emerged or expanded. Even when aggregated overall developing countries, the contribution of export taxes and import subsidies to the overall WRI rises and falls with international prices, whereas the opposite is true of import taxes and export subsidies.

Why Governments Distort Agricultural Markets the Way They Do?

Much of the variations in policy interventions over time and across sectors, individual commodities, and alternative policy instruments revealed above can be explained using the lens of political economy. Various schools of thought in political economy have provided insights into the conflicts between the public interest and special interests that naturally emerge in the design and implementation of public policies, including those that affect agricultural and food markets. These are used to explain several of the stylized facts presented in the section Policy Impacts on Agricultural Prices.

Income Redistribution

Distortions in agricultural and food markets result from policies designed to alter the distribution of income from what would otherwise emerge under unfettered market outcomes. Income distribution may change for structural or cyclical reasons. For example, overall economic development is typically associated with some sectors growing and some declining faster than others. In addition, agricultural markets and food prices fluctuate around longer term trends, causing important short-term changes in income and welfare distribution. Historically, this has induced governments to intervene in order to (partially) offset these market developments. This tendency involves increasing import tariffs or export subsidies when market prices decline and suspending import tariffs or export subsidies (or increasing export taxes or import subsidies) when market prices rise.

Changes in incomes in different sectors (or between different groups in society) create political incentives – both on the demand (farmers' and consumers') side and the supply (politicians') side – to exchange government transfers for political support. When farm incomes from agricultural markets decline relative to producers' incomes in other sectors, farmers are more likely to seek nonmarket sources of income such as government support. They do so either because the return on investment is greater from lobbying activities than from market activities (because the willingness to vote for and support politicians grows as the political rents that are generated increase) or because aversion to loss determines political reactions (Tovar, 2009; Swinnen, 1994; Baldwin and Robert-Nicoud, 2007).

Reduction of Agricultural Disincentives in Developing Countries

The observed correlation between RRAs and economic development can be explained largely by fundamental economic forces, including growth, structural adjustments, information costs, and changes in governance structures.

Economic growth, restructuring, and political incentives

Economic structural factors other than income distribution affect political incentives. In a poor economy, most workers are agricultural, and laborers (especially nonfarm laborers)

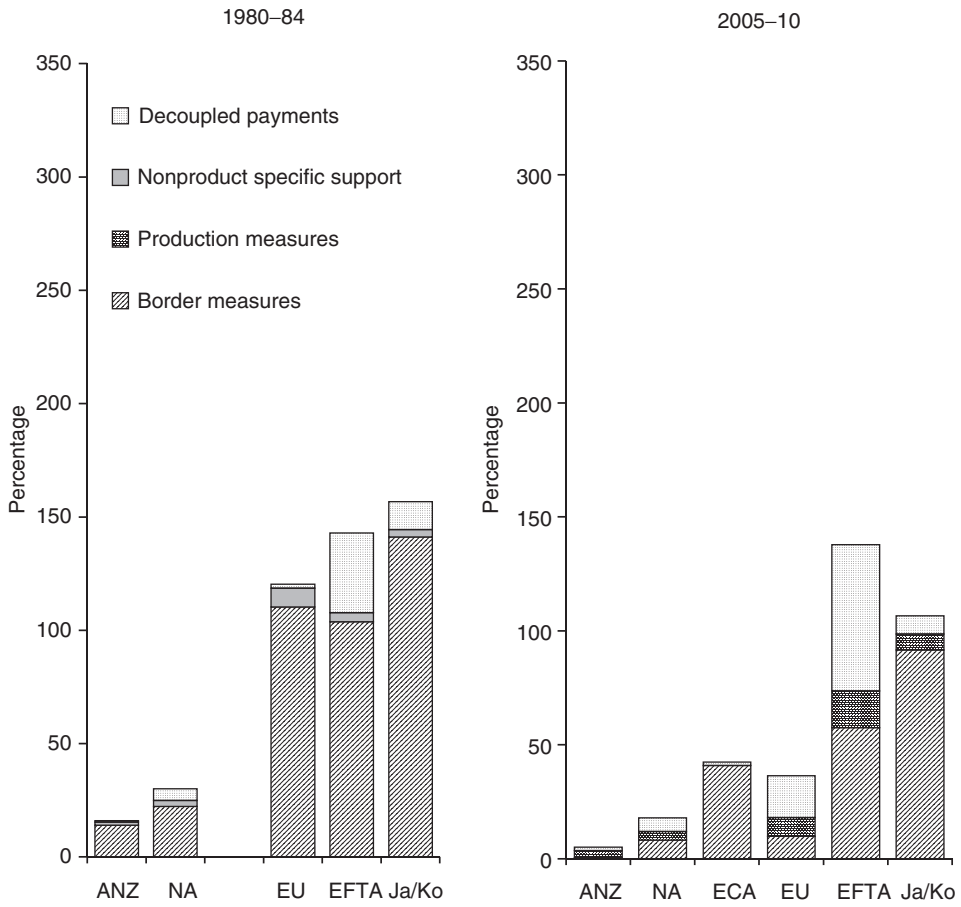

Figure 9 Comparison of earlier (1980–84) and more recent (2005–10) contributions of various policy instruments to the producer component of the welfare reduction index (WRI) for selected high-income and transition countries (%). ANZ, Australia and New Zealand; EFTA, European Free Trade Area; EU, European Union of 27 member countries; Ja/Ko, Japan and (South) Korea; and NA, North America. ECA is a term used by the World Bank to denote the transitional economies of Central and Eastern Europe and Central Asia. Reproduced from Croser, J.L., Anderson, K., 2011. Changing contributions of different agricultural policy instruments to global reductions in trade and welfare. World Trade Review 10 (3), 297–323, updated using Anderson, K., Nelgen, S., 2013. Updated National and Global Estimates of Distortions to Agricultural Incentives, 1955 to 2011. Available at: www.worldbank.org/agdistortions (accessed 29.04.14).

spend a large share of their income on food. Accordingly, the benefit to industrialists of a border tax – regardless of whether it targets manufacturing imports or food exports – is proportionately far greater than the loss it imposes on farm income. By contrast, in an advanced industrial economy, in which a lower percentage of workers labor on farms and in which workers generally spend a small share of their income on farm products, a rise in the relative price of farm products benefits farm households proportionately far more than it harms nonfarm households and industrialists (Anderson, 1995, 2010; Anderson *et al.*, 1986). The per-unit political cost of increasing farm incomes by raising the RRA thus decreases as the economy becomes less agrarian. In other words, even though the share of farmers in the voting population declines, less opposition to protecting farmers arises when there are fewer of them (Swinnen, 1994).

Democratization

Many developing countries have experienced democratization over recent decades. The implications for agricultural policies are not straightforward. The very factors that make it difficult for farmers to organize politically (such as their large number and geographic dispersion) render them potentially powerful in electoral settings (Bates and Block, 2010; Varshney, 1995). Because greater insulation of decision-makers implies that they can follow their personal preferences to a greater extent in selecting policies, their ideologies or other types of preferences are a key variable. This has little predictive power in the absence of specific information about those preferences. One implication, however, is that if dictatorial leaders are less constrained in setting policies, all else constant, there should be more variation in observed policy choices under dictatorial regimes than under democracy.

Swinnen *et al.* (2001) show that changes in electoral rules that have disproportionately benefitted agriculture (e.g., extending voting rights to small farmers and tenants in the early twentieth century) have induced an increase in protectionism. In contrast, other electoral changes have not affected agricultural protection because they increased the voting rights of both those in favor and those against farm protection.

Olper *et al.* (forthcoming) exploit the time-series and cross-sectional variation in the World Bank's database to show that democratization reduced agricultural taxation and increased agricultural subsidization because most political transitions occurred in poor countries with many farmers.

Lobby organization of farmers, agribusinesses, and consumers

Improvements in rural infrastructure have affected agricultural interests' ability to organize for political action. Regardless of governance structures, in order to influence political choices effectively, interest-group members must act in unison. For their collective action to yield meaningful results, organizational structures must be established that can mobilize resources and direct individual action. The greater the number of politically active members in an organization whose interests are aligned, and the more resources at the organization's disposal, the greater will be its political power base.

Olson's (1965) collective-action theory predicts that in poor countries, food consumers (net buyers of food) will wield more political power than farmers (and even more than the subset of net sellers of food). Consumers are often concentrated in cities, where political coordination and enforcement costs are more favorable than is the case in rural areas where farmers reside. However, as the economy develops – and especially as the share of agriculture in employment declines and rural infrastructure improves – the cost of political organization for farmers decreases. This cost reduction is likely to increase the effectiveness of farmers' representation of their interests and, as a consequence, of their lobbying activities.

Researchers debate whether changes in relative collective-action costs can explain major changes in agricultural policies. Although rural infrastructure and information have improved significantly as countries have developed, even in developed countries, the number of farmers remaining is still very large.

The growth and concentration of agribusinesses and food-processing companies, which are sometimes aligned with farm interests in lobbying for agricultural policies, serve to strengthen pro-farm interests (Anderson, 1995; Rausser *et al.*, 2011). Because farm lobbies and agribusiness interests can coalesce and are increasingly well capitalized and concentrated, they have been an important force in orchestrating public policies that benefit their interests (Gawande and Hoekman, 2006; López, 2008). In Europe, the growth of agricultural protection has been associated with the growth of cooperative agribusiness and food-processing (and even transport and storage) companies (Swinnen, 2008).

Rural communication and mass media

Information plays a crucial role in political markets, organization, and policy design. Downs's (1957) 'rationally ignorant voter' principle means that it is rational for voters to be ignorant about certain policy issues if the costs of information are higher than the (potential) benefit of being informed. This argument immediately implies that policies will be introduced that create concentrated benefits and dispersed costs, because the information costs are relatively large for those who carry the burden of financing transfers and relatively small for those who receive the benefits (Rausser, 1992). As a result, forces that change information costs may cause changes in public policies, including agricultural protection. One example is enhanced rural communication infrastructure, which occurs either through public investments (as in many high-income countries earlier in the twentieth century) or through technological innovations and commercial distributions (as in the recent dramatic increase in mobile-phone use in rural areas of developing countries).

Another influencing factor is the spread of commercial mass media (McCluskey and Swinnen, 2010). While television and radio were always commercial in countries such as the US, this was not the case in many other countries where, until relatively recently, radio and television were mostly publicly owned (and many newspapers were linked to political parties). Access to mass media empowers people politically, and a more informed and politically active electorate increases the incentives for a government to be responsive (Besley and Burgess, 2001; Strömberg, 2004).

Mass media can alter the landscape of political competition. Group size (e.g., the number of farmers vs. the number of food consumers in the economy) helps determine lobbying effectiveness. Mass media alter these mechanisms by providing more information to larger groups (Kuzyk and McCluskey, 2006; Oberholzer-Gee and Waldfogel, 2005). Strömberg (2001, 2004) shows that mass media bias their information toward groups that are more attractive to advertisers.

Olper and Swinnen (2013) argue that mass media will increasingly weaken the political power of small groups (in rich countries, farmers; in poor countries, consumers) and reinforce that of large groups and groups attractive to advertisers (in rich countries, consumers and urban interests; in poor countries, farmers). Thus, mass media favor rural interests (thus leading to higher RRAs) in poor countries but urban interests (thus leading to lower RRAs) in rich countries.

Structural-adjustment programs and policy conditionality

Another key issue is the impact of international financial institutions (such as the World Bank and the International Monetary Fund) and the policy conditions they impose on developing countries as part of their lending. The structural-adjustment programs in Africa and Latin America in the 1980s and the programs in the transition countries in Europe and Asia in the 1990s often required the borrowing governments to liberalize their policies and reduce distortions. Some policy reforms were reversed after the loans were in place, but many appear to have stuck (Akiyama *et al.*, 2001; Kherallah *et al.*, 2002).

In the transition countries of Europe and Central Asia, this shift has caused a significant reduction of subsidies to agriculture (Anderson and Swinnen, 2010). In Sub-Saharan Africa, the structural-adjustment programs are partially responsible for a significant reduction of taxes on farmers (an estimated average increase in RRAs of approximately 20% points, according to Swinnen *et al.*, 2011).

Summary

The reduction of antiagricultural policies in developing countries during the past decade has been caused by economic growth, by the shift in the political–economic equilibria induced by such growth, and by changes in governance and

media structures. As rural infrastructure improves and communications costs fall, farmers become more aligned and politically more effective. This development again contributes to a shift in the power balance in favor of rural interests. Moreover, as economies develop, the role of agribusiness and food companies – often with cooperative roots – expands. These more concentrated and better capitalized organizations often form powerful lobby coalitions with farmers' interest groups. Reduced taxation of agriculture in many developing countries that experienced income growth during recent decades is consistent with the identified forces sourced with a political-economic lens. The reduction of antiagricultural policies over the past two decades has been reinforced by political reforms (democratization) and by the growth of commercial media.

Reduction of Agricultural Subsidies in High-Income Countries

RRAs increased as incomes grew from the 1950s to the mid-1980s. But since then, there has been a change in trend. The latter shift has been particularly pronounced in the EU. Several factors seem to have played a role in this recent reversal in higher income countries, including the WTO, information and mass media, and EU-specific effects.

Agricultural policies were integrated in the WTO as part of the Uruguay round agreement on agriculture (URAA) in 1994. The impact of the URAA differs strongly between countries that participated in the negotiations and those that joined later. For the countries that participated in the Uruguay round, the URAA may have constrained the growth of agricultural protection afterwards (Anania *et al.*, 2004; Swinnen *et al.*, 2012). However, the WTO's impact on agricultural policy in, for example, the US over the past two decades has been very limited (Orden *et al.*, 2010).

The URAA's effects were different for countries that joined after the WTO's creation or went through institutional changes that affected their WTO constraints. For example, the WTO conditions imposed on China and Russia during their WTO accession processes have been much more stringent than was the case for some of the older WTO members (Drabek and Bacchetta, 2004; Evenett and Primo Braga, 2006).

In the EU, new countries' accession has required reforms of the EU's agricultural policy in order to avoid conflicts with the WTO. Although probably the most important aspect of the reforms has been a shift to less trade-distorting instruments, a substantial decline in the EU's RRAs has also occurred. The RRA declined from approximately 70% in the 1980s to less than 40% at the turn of the century, and, for the core 15 countries, to 11% in 2005–10 (**Figure 7**).

Since the 1980s, mostly poorer countries have joined the EU (e.g., Spain, Portugal, and Greece in the 1980s, and ten East European countries in the 2000s), apart from the three rich but small ones that joined in 1995. This has reduced the pressure to increase RRAs. In addition, several of these countries were not part of the GATT, and their integration in the EU caused GATT constraints for the Union as a whole in the 2000s. These constraints generated pressure to reduce total agricultural support. In high-income countries generally, the growth of commercial mass media may have played a role in reducing RRAs. Whereas the effect of mass media in developing countries is to reduce agricultural taxation, in rich countries, mass media typically help reduce agricultural support. Olper's and Swinnen's (2013) findings imply that by increasing government accountability, competition in the mass-media market often reduces distortions to agricultural and food prices.

A Shift to (More) Decoupled Subsidies in High-Income Countries

Reinstrumentation of assistance has occurred in some but not other high-income countries, involving a movement away from market-price support toward domestic decoupled measures (**Figure 9**).

The selection of policy instruments is influenced by several factors. First, different instruments imply different deadweight costs in redistribution. When exports are large, countries are more likely to use nondistortionary or less distortionary instruments than border measures (Swinnen *et al.*, 2012).

Policy instruments also differ in implementation costs. Trade taxes (either import tariffs or export taxes) are easiest and least costly to implement (Dixit, 1996; Rodrik, 1995). In many developing countries, the system for administering and enforcing income taxes or subsidies in the past may have been too costly to implement. Governments will choose trade (and market) interventions less often as their administrative capacity to tax and subsidize incomes improves.

Accessions to the GATT and WTO may have influenced the nature of the policy-instrument interventions more than the total level of policy transfers. Because a key purpose of the WTO is to reduce trade distortions, accession to the WTO should cause a shift toward less trade-distorting policies.

Because the decline in the EU's RRAs plays an important role in the overall RRA decline of high-income countries (**Figure 7**), the URAA (and later WTO Doha Round) negotiations have triggered an important change in agricultural policy-instrument choice in the EU over the past decades: a shift in the 1990s from price support to direct payments and to decoupled payments in the 2003 Reform of the CAP. These consecutive reforms strongly reduced the trade distortions.

The URAA has had less impact on US agricultural policies. Nonetheless, the US administration has attempted reforms to insure that many US agricultural subsidies are classified as 'green box' (i.e., nontrade distorting) under the WTO agreement (Orden *et al.*, 2010). In this sense, the motivation for its policy reforms appears to be similar to the EU's. These common outcomes for both the EU and the US suggest that WTO constraints could play an increasingly important role in reducing distortions if a substantive agreement could be reached in the current Doha Round. Such WTO constraints also induce emerging countries (such as China) to choose nondistorting (or less distorting) policy instruments as they attempt to support the incomes of agricultural households.

Finally, the revenue motive for governments will also affect the choice of policy instruments. If the tax infrastructure is less developed, governments have greater incentives to use tariffs

instead of direct income support to assist farmers. Rich countries have used value-added taxes more efficiently, and new information technologies have lowered the cost of providing decoupled payments to targeted groups (Alatas *et al.*, 2012).

Differences in Assistance between Commodities

Why is intrasectoral dispersion of NRAs so large in so many countries? Why are some commodities (rice, dairy, and sugar) assisted in virtually all countries (**Figure 6**)? There are several reasons to expect differences in NRAs not only among countries but also among specific agricultural commodities within a country. One explanation is that, for reasons similar to those that underlie countercyclical support, governments are more likely to support (sub-)sectors with a comparative disadvantage (imports) than (sub-)sectors with a comparative advantage (exports). Differential effects on government revenues also help explain why taxation is higher for specific commodities that are net exported: tariff revenues and export taxes increase government revenues, and, in the case of larger economies, improve their terms of trade, whereas trade subsidies do the opposite. Moreover, in poor countries in which tax-collection institutions are weakly developed, trade taxes (either import tariffs or export taxes) are often an important – or the only substantive – source of tax revenue.

Demand and supply characteristics matter as well. Raising tariffs on commodities that are more important for consumers, such as staple foods, will be opposed more often than will raising tariffs on commodities that are less important as a consumption item, and vice versa for producers. Demand and supply elasticities also affect the distortions and costs of policies (Gardner, 1983, 1987; Rausser and de Gorter, 1989; de Gorter *et al.*, 1992). The distortions (deadweight costs) and budgetary costs of policy intervention typically increase with higher supply elasticities and with the commodity's trade balance (that is, when its net exports increase). Because of the inherent changes in the distribution of costs and benefits of policies and the associated political incentives, political-economy theories predict that sectors with higher supply elasticities will be subsidized less often (or taxed more often) and that commodity support is negatively related to supply elasticities. Again, these factors are likely to affect also the choice of policy instruments, as, for example, when governments restrain supply responses through such additional regulations as marketing quotas and/or land controls (Rausser, 1992; Rausser *et al.*, 1984).

Another explanation is that the costs of implementing (and enforcing) certain policies can be quite different because of differences in the way commodities are marketed. For example, commodities that are perishable and require processing, such as sugar and dairy products, are typically marketed through processing companies – a point at which governments can intervene at relatively low cost. In contrast, it can be more costly to intervene in the case of products that are easily storable and which farmers can market directly to consumers (or to other farmers).

Finally, governments have treated perennial crops differently than annual crops (McMillan, 2001). Once farmers have incurred the costs of establishing a perennial plantation, they will continue to produce the exportable crop as long as the price they receive covers incremental or harvesting costs (Gawande and Hoekman, 2010).

Prospects for Further Policy Reforms

From our assessment, it is clear that much progress has occurred in the past decade or so in improving our understanding of why governments distort incentives facing agriculture. Certainly, more empirical testing of hypotheses suggested by theorists could be carried out, but considerable light has already been shed on most of the stylized facts raised by the World Bank's documentation of the evolution of global price distortions since the 1950s. That understanding suggests that there is room for cautious optimism about the prospects for future agricultural policy reform. Admittedly, it is troubling that some developing countries have moved from negative to positive RRAs and that agricultural protection and market distortion have recently increased in three of the most important developing countries, namely China, India, and Indonesia. In high-income countries, too, although the World Bank data reveal declining trends for NRAs, these trends do not necessarily reflect actual changes in their distorting policy instruments. Instead, higher world food prices largely explain the reductions in measured NRAs in the past 5 years. But many other countries' RRAs do appear to have converged toward zero (that is, where their assistance to agricultural and nonagricultural tradables is approximately equal), and other high-income countries have been lowering their RRAs nontrivially since the late 1980s.

Global and regional institutions appear to have played an important role in contributing to these reforms. Of particular importance to the decline in the RRA for the EU has been the institution of the General Agreement on Tariffs and Trade (and now the WTO). However, the recent shift in agricultural policies focusing on renewable energy (particularly in the USA, the EU, and Brazil) has major implications for world food prices and security. Ongoing research should make as transparent as possible the continued pursuit of protectionist measures by various countries in the form of biofuels policies, which tend to raise world food prices, in contrast to traditional agricultural policies, which historically have depressed these prices.

Prospects for policy reform will be influenced by the changing landscape of organized economic interests. Interactions between farmers and landowners, agribusiness, food and retail companies, environmentalists and other groups clearly influence agricultural policy negotiations and debates in all countries. The vertical relationships between farmers and agribusinesses are often critical in sustaining policy reforms. Capturing opportunities to form new coalitions among the interests of farmers, downstream agribusiness, food consumers, and environmental groups will largely dictate sustainable policy reforms that promote the provision of local public goods, agricultural productivity, and markets for environmental services. Certainly the many complex factors that contribute to distortion of agricultural and food markets can impede as well as promote progress, but hopefully continued

reform of entrenched policies and practices, along with heightened scrutiny of new developments, will promote greater transparency and cooperation.

Acknowledgments

Agroforestry: Complex Multistrata Agriculture

G Schroth and M do Socorro Souza da Mota, Santarém, Pará, Brazil

© 2014 Elsevier Inc. All rights reserved.

Glossary

Agroforest Complex agroforestry system with a forest-like structure; synonymous to complex multistrata agroforestry system.

Complex multistrata agroforestry system (CMSAF) Tree-dominated land use system with two or more strata of trees or shrubs and a substantial degree of structural complexity within at least one of the strata.

Homegarden Intimate, multistorey combination of various trees and crops, sometimes in association with domestic animals, around homesteads.

Remnant vegetation Plants remaining from previous forest when the vegetation was cleared for planting. They can make a significant contribution to the composition, especially of CMSAF with understorey tree crops.

Shade trees, shade canopy Upperstorey in a system with understorey tree crops; usually fulfills various functions such as production of timber and nontimber tree products besides shading.

Traditional knowledge and practice Knowledge and practice which have been used for time periods ranging from decades to millennia by local people.

Introduction and Definition

Complex multistrata agroforestry systems (CMSAF) are tree-dominated land use systems with two or more strata of trees or shrubs and a substantial degree of structural complexity within at least one of the strata. This structural complexity is usually the result of a mix of species and age classes. Simple two-strata systems consisting of a monospecific understorey of tree crops and an equally monospecific overstorey of planted shade trees or other tree crops (say, cocoa under coconuts or coffee shaded by one legume tree species) are not included here in CMSAF, although the limits are not well defined. The economically dominant species in CMSAF are mostly planted, and this distinguishes these systems from managed natural forests. However, CMSAF can contain a significant number of spontaneous trees, shrubs, vines, epiphytes, and other plants that are remnants of the vegetation that was cleared to make place for the agroforestry system or its regeneration. Other species were brought in through natural seed dispersal or regenerated from the planted trees under the canopy or in clearings. The survival and growth of these species, many of which may also have commercial or subsistence uses, depends on their shade tolerance and management of the system.

In many parts of the humid and subhumid tropics and some savannah areas, CMSAF are a traditional way of growing tree crops. Four basic types of CMSAF are classified here:

1. CMSAF based on shade-tolerant understorey crops such as cocoa (*Theobroma cacao*), coffee (*Coffea* spp.), tea (*Camellia sinensis*), or cardamom (*Elettaria cardamomum*) grown under a complex and often species-rich canopy of native and/or planted trees.
2. CMSAF based on overstorey crops such as rubber (*Hevea brasiliensis*), damar (*Shorea javanica*), or durian (*Durio zibethinus*) grown under extensive management that allows the development of a substantial amount of native vegetation that forms most of the understorey and also mixes with the main tree crop in the overstorey.
3. Mixed systems of understorey and overstorey tree (and other) crops such as homegardens where the complexity of the vegetation is the result of high diversity of planted species that are often intensively managed.
4. Disturbed natural forests that are locally enriched with planted tree crops, but where the native vegetation predominates.

The complex structure of CMSAF can thus result either from extensive management and tolerance of natural vegetation where it does not interfere too much with the main commercial species and harvest operations (types 1, 2, and 4) or from intensive management, as is the case in homegardens (type 3). In the latter, a range of under- and overstorey species are intentionally planted and managed together in a complex spatial and temporal arrangement.

CMSAF with a large percentage of natural vegetation have also been termed 'agroforests' by Michon and de Foresta (1999) and Schroth *et al.* (2004c) in reflection of their forest-like characteristics. Some types of CMSAF are almost indistinguishable from natural forest to the untrained eye, especially if seen from a distance or from above (**Figure 1**). There are, however, also clear differences between even the most complex CMSAF and natural forest, as discussed in the Section on Types, Composition, Distribution, and Temporal Dynamics of CMSAF.

CMSAF are remarkable among agroforestry systems for their high diversity, which is either of cultivated species and varieties ('planned biodiversity') or of native species of plants and fauna ('unplanned biodiversity'), or sometimes both. They are also among the land use systems that are most likely to hold carbon stocks and perform hydrological functions relatively close to those of natural forests. The provision of these environmental services by these traditional agroforestry systems has attracted some attention with regard to how and to what degree the management of these systems can be intensified to increase their production and hence the living standards of their owners, but at the same time conserving their environmental service roles. This can be thought of as

Figure 1 Shaded cocoa agroforest (cabruca) in southern Bahia, Brazil. Reproduced from (with kind permission from Springer Science and Business Media) Schroth, G., Faria, D., Araujo, M., *et al.*, 2011b. Conservation in tropical landscape mosaics: the case of the cacao landscape of southern Bahia, Brazil. Biodiversity and Conservation 20, 1635–1654.

'ecological intensification.' These questions will be briefly reviewed in the Section on Production and Intensification.

Types, Composition, Distribution, and Temporal Dynamics of CMSAF

CMSAF Based on Understorey Crops

Moderately, shade-tolerant tree crop species such as cocoa, coffee, and tea are grown in a wide variety of land use systems. These range from unshaded and sometimes irrigated monocultures at one extreme of a gradient of increasing complexity through simply structured shaded systems consisting of a monospecific understorey of the tree crop and an often equally monospecific overstorey of planted shade trees to CMSAF and even natural forest where these species are native, at the other extreme (Figure 2). The use of shade is a traditional practice in many regions where these crops are grown. It has a number of benefits in terms of microclimatic protection, maintenance of nutrient cycles, and biological processes such as pollination and pest control, especially where no agrochemicals are used (Schroth *et al.*, 2001; Tscharntke *et al.*, 2011). For example, early attempts to grow cocoa in West Africa with little or no shade failed because of the intensity of insect attack that required the use of synthetic pesticides (Schroth *et al.*, 2000). Even intensively managed tree crop systems often use some shade, typically leguminous tree species such as *Erythrina* spp., *Inga* spp., *Gliricidia sepium*, or *Leucaena leucocephala*. These species are nitrogen fixing, are easy to establish, and can be conveniently lopped for shade adjustment and increased nutrient recycling. Where hurricanes are frequent, as in the Caribbean, they can grow back even after severe damage. They are also often present as a middle stratum in CMSAF. Unfortunately, some tree species, including *L. leucocephala*, have become invasive in regions where they were introduced as shade trees (Richardson *et al.*, 2004).

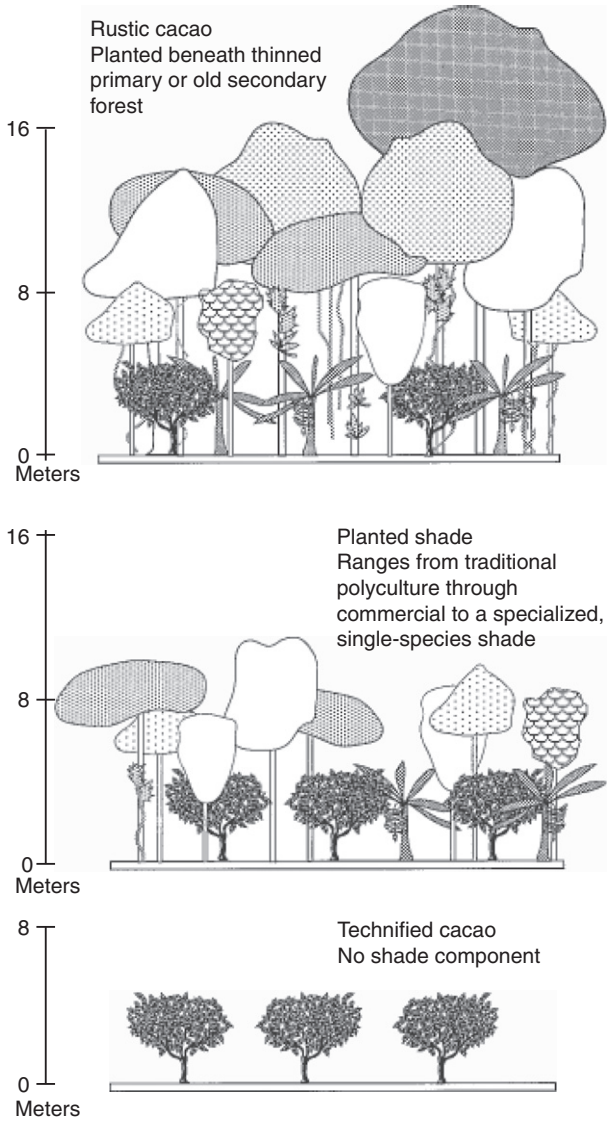

Figure 2 Gradient of cocoa production systems with varying degrees of complexity. Reproduced from (with kind permission from the Royal Swedish Academy of Sciences) Rice, R.A., Greenberg, R., 2000. Cacao cultivation and the conservation of biological diversity. Ambio 29, 167–173.

The canopy of CMSAF with understorey tree crops is often composed in part of remnant primary or secondary forest trees, or the natural regeneration from them, that were retained when tree crops were first planted. The remnant trees may have been retained either because they were considered useful (e.g., for food, medicine, or timber) or because they were difficult and laborious to fell (de Rouw, 1987). In addition, interplanted fruit trees are often present. Such systems also allow for periodic abandonment of the crops at times of low prices. For example, in Bahia, Brazil, the practice of cocoa planting into thinned forest ('cabruca') evolved as a labor-saving practice that was maintained even when extension services recommended clearfelling of the forest and planting of exotic leguminous shade trees (Johns, 1999). In these cabrucas, cocoa grows under a mix of native trees, planted leguminous

shade trees, and fruit trees, such as the exotic jackfruit (*Artocarpus heterophyllus*) and cajá (*Spondias mombin*), the latter introduced from the Amazon. These fruit trees are particularly prominent because they are preferred by farm workers and can regenerate spontaneously, especially during phases of extensive management or temporary abandonment (Sambuichi *et al.*, 2012). Bananas (*Musa* spp.) are also often present. There is also a recent trend of enriching the cabrucas with other commercial tree species, such as rubber trees (Schroth *et al.*, 2011b).

There is a wide variety of cocoa production systems in West and Central Africa, with a clear east–west gradient of decreasing shade use. According to Gockowski and Sonwa (2008), medium to heavy shade (i.e., CMSAF) is used by more than 50% and 60% of cocoa farms in Nigeria and Cameroon, respectively, but less than 30% of cocoa farms in Ghana and Côte d'Ivoire. Within Ghana, Ruf (2011) reported a trend of decreasing shade use on cocoa farms from the older, eastern cocoa regions to the newer, western cocoa regions. This changing attitude toward shade is apparently related to the adoption of cocoa varieties that are less shade tolerant as well as related to forest laws that restrict the farmers' rights to selling farm timber. The use of shade has also been in decline in Côte d'Ivoire, in part related to the dominant role of migrant farmers from nonforest areas during the expansion of the cocoa sector in the second half of the twentieth century (Ruf and Schroth, 2004). Differences in the attitude toward, and knowledge about, forest trees as cocoa shade between local and migrant cocoa farmers have also been shown in Cameroon (Laird *et al.*, 2007). In southern Cameroon, where CMSAF are the dominant practice in cocoa farms, trees of other species contributed 25% to total farm revenues (Gockowski *et al.*, 2010). A trend of increasing replacement of forest trees with fruit trees with increasing proximity to the capital Yaoundé has been observed. This suggests that farmers intensify and diversify their cocoa systems as they gain market access for a wider range of products (Sonwa *et al.*, 2007).

Coffee and tea are also sometimes grown in CMSAF, although the most complex types are perhaps less frequent than those with cocoa. In the case of coffee, systems with a large percentage of native forest trees in the canopy are also called 'rustic systems' or 'traditional polycultures,' whereas systems with a dominance of planted and managed fruit and timber trees (including bananas and plantains) in the canopy are referred to as 'commercial polycultures' (Moguel and Toledo, 1999). CMSAF with coffee can be found in several parts of Mesoamerica, including the Sierra Madre de Chiapas in southern Mexico, where Arabica coffee is often interspersed with forest and fruit trees and sometimes with ornamental palms (**Figure 3**). This forms a landscape mosaic made up of coffee agroforests, natural forest, and cattle pasture (Schroth *et al.*, 2011a). In El Salvador, most of the 'forest' cover consists of coffee agroforests (Somarriba *et al.*, 2004). A common practice in Costa Rica and other parts of Central America is the association of coffee with commercial timber trees, especially laurel (*Cordia alliodora*) as well as fruit and leguminous shade trees. In India's main coffee region, Kodagu in the Western Ghats mountains, coffee is often grown under a highly diverse canopy of native forest trees that were retained when coffee was planted into partially cleared forest, as well as fruit trees

Figure 3 Mixed agroforest of coffee (*Coffea arabica*) and ornamental palms (*Chamedorea* sp.) in the Sierra Madre de Chiapas, Mexico. Reproduced from (with kind permission from Springer Science and Business Media) Matocha, J., Schroth, G., Hills, T., Hole, D., 2012. Integrating climate change adaptation and mitigation through agroforestry and ecosystem conservation. In: Nair, P.K.R., Garrity, D.P. (Eds.), Agroforestry – the Future of Global Land Use. Dordrecht: Springer, pp. 105–126.

such as jackfruit, areca nut (*Areca catechu*), coconut (*Cocos nucifera*), and bananas. In this region, the coffee area has doubled in the past 35 years, often at the expense of private forests (Garcia *et al.*, 2010). Coffee is a component of some traditional multistrata agroforests in East Africa, such as the Chagga homegardens on Mount Kilimanjaro that are now suffering from increasing population pressure leading to land fragmentation and species loss (Kumar and Nair, 2004). In Guinea in West Africa, coffee agroforests form bands around villages where they were planted either in forest fallows or by reforesting savannah land. They are composed of an understorey of Robusta coffee (*Coffea canephora*), a middle stratum of fruit trees such as cola (*Cola nitida*), avocado (*Persea americana*), plantains (*Musa* spp.), etc. and an overstorey of timber trees and oil palm (*Elaeis guineensis*) (Correia *et al.*, 2010).

Miang tea, for chewing, is grown in traditional CMSAF in mountain villages of northwestern Thailand as well as in parts of China. In Thailand, the secondary forest is enriched with tea bushes, associated with other crops and sometimes cattle, forming a belt on mid-slope between the homegardens around the villages in the valleys and the mountain forest. When these systems are abandoned because of labor shortage, they gradually revert to forest (Schroth *et al.*, 2004c).

CMSAF can also involve herbaceous understorey crops as their principal commercial species. For example, in various parts of Asia and East Africa, cardamom (*E. cardamomum*) is grown in the understorey of thinned forest after removing the native understorey vegetation (**Figure 4**). The management of such systems can be relatively intensive, involving weeding and fertilizing the cardamom. Canopy opening and understorey clearing increase the germination and growth of pioneer species, including exotic species, so that the tree species composition of such agroforests can differ substantially from that of natural forest (Dhakal *et al.*, 2012; Hall *et al.*, 2011).

Figure 4 Cardamom (*E. cardamomum*) agroforest in Sri Lanka. (Photo: Glatzel, G., unpublished, with kind permission)

Depending on the size of the planting and the intensity of the disturbance and management, these systems can form a transition between CMSAF based on understorey crops and forest-enrichment systems that are discussed in the Section on Forest-Enrichment Systems.

CMSAF Based on Overstorey Crops

Tree crops which form the upperstorey canopy when they are productive are also grown in a wide range of systems and management intensities. For instance, although rubber latex is frequently produced by trees grown in monoculture plantations, it is also still extracted from native forest trees in parts of the Amazon. It is also produced in CMSAF land use systems of intermediate intensity, such as the rubber agroforests which have been independently developed by small farmers both in Indonesia and the Amazon by integrating these trees into their slash-and-burn rotational systems with food crops. In the Tapajós valley of the Brazilian Amazon, this type of rubber agroforestry was probably developed during the rubber boom late in the nineteenth or very early in the twentieth century (Schroth *et al.*, 2003). Rubber seeds are initially planted with cassava (*Manihot esculenta*) or sometimes other food crops. When annual cropping stops after approximately 2 years, the rubber seedlings are occasionally weeded until they can compete with the fallow regrowth. Tapping begins after approximately 8 years (sometimes earlier) and requires the clearance of paths between the rubber trees, whereas elsewhere the secondary forest is allowed to develop (**Figure 5**). This system is still being practiced, although many of these agroforests are now inactive. Interruption of the tapping during the dry season and during times of low rubber prices in combination with the extensive management practices results in the formation of secondary forests enriched with rubber trees. These cover large parts of the river banks of the Tapajós and neighboring rivers to the present day (Schroth *et al.*, 2003).

In Indonesia, rubber agroforests have evolved on the islands of Borneo and Sumatra soon after the introduction of the rubber tree from Brazil in 1910. Rubber seedlings are planted into slash-and-burn plots with dryland rice (*Oryza sativa*), otherwise the management is very similar to that in the Brazilian rubber agroforests (Gouyon *et al.*, 1993; Michon, 2005). However, in contrast to Brazil, smallholder rubber agroforests soon took over from large estates to become the dominant form of rubber cultivation in Indonesia (de Jong, 2001), covering 2.5–3 million hectare, supplying more than 70% of the rubber produced in the country and providing income to some 5 million people. In these Indonesian agroforests, the density of rubber trees is initially approximately 500–600 trees per hectare when tapping begins. It then falls progressively through tree mortality due to root rots, fungal diseases of the tapping panel, and other accidents (in one study 200 trees per hectare remained even after 40 years). When tapping becomes unprofitable, the agroforest is clearfelled, burnt, and the site is replanted with food crops and new rubber seedlings. Because replanting and concomitant loss of income from the surviving rubber trees is a major investment for small farmers, plantation is often delayed; moreover some agroforests have reached even 80 years of age. In some cases, farmers try to regenerate the light-demanding rubber trees in small clearings. At present, these traditional systems are being progressively replaced by more intensive practices, such as planting monoculture rubber and oil palm (Gouyon *et al.*, 1993; Michon, 2005). In the Amazon, the temporal dynamics of rubber agroforestry have not been studied to the same extent as that in Indonesia, but it is clear that they also can be, to a great extent, more than 50 years old, and the system appears to be less cyclical than the Indonesian equivalent, probably because of lower population pressure (Schroth *et al.*, 2003). As mentioned above, rubber trees have also been integrated in shaded cocoa systems in Bahia, Brazil, as a way of intensifying management and increasing revenues. Rubber has become a common diversification option for cocoa farmers in West and Central Africa, although more commonly through planting in separate plots rather than interplanting with cocoa (Ruf, 2013).

Rattan (*Calamus* spp.), a genus of climbing palms, is another example of a perennial crop that has been successfully

Figure 5 Rubber agroforest of unknown age in the Tapajós National Forest, Brazilian Amazon. Old tapping marks are visible on several trees in the left half of the picture. Reproduced from (with kind permission from Island Press) Schroth, G., da Fonseca, G.A.B., Harvey, C.A., *et al.*, 2004b. Introduction: the role of agroforestry in biodiversity conservation in tropical landscapes. In: Schroth, G., *et al.* (Eds.), Agroforestry and Biodiversity Conservation in Tropical Landscapes. Island Press, Washington, pp. 1–12.

integrated into the shifting cultivation cycle in Indonesia, especially Eastern Kalimantan, where it has become the second most important forest product of the country after timber. The rattan seeds or seedlings are added to slash-and-burn plots with dryland rice and they grow as part of a commercial fallow vegetation when the food crop fields are abandoned. Canes can be harvested after 7–10 years for 50 or more years, until the plot is slashed and burned again for a new cycle. This practice is now threatened by the expansion of oil palm as well as periodic droughts to which rattan is poorly adapted (Michon, 2005).

Rattan and rubber agroforests in Indonesia, and to a lesser extent rubber agroforests in the Amazon, can be considered long-cycle rotational systems that involve periodic events of clearfelling and replanting – in fact a type of economically enriched fallow. Their invention is a remarkable case of farmer innovation. Through the integration of tree crops into their slash-and-burn systems, farmers in Indonesia and the Amazon solved several problems at the same time. The planting of tree seeds or seedlings with food crops required a little extra labor during the first few years, when the seedlings were most vulnerable. In contrast to the practice used in industrial plantations of planting tree crops with cover crops, it also ensured food security while the tree crops were not yet productive. Furthermore, the agroforests had a much higher density of useful trees than natural forest, where the tree crops were native (e.g., several hundred rubber trees per hectare in agroforests as compared with less than five per hectare in natural forest in the Amazon), thereby again increasing the productivity of labor as well as land. And finally, by associating tree crops with native vegetation, these economically enriched fallows regenerated the fertility of the site, enabling a new cycle of food and tree crops when the old tree crops had been exhausted.

Other CMSAF that are planted in slash-and-burn plots can become permanent through regeneration in canopy gaps, as in natural forest. Remarkable among these are the agroforests based on damar trees (*S. javanica*), a resin producing dipterocarp species that occupy more than 50 000 ha in southern Sumatra (Michon, 2005). Permanent damar agroforests were invented by farmer extractivists in southern Sumatra in response to the overexploitation of damar trees in the native forest when market demand for their resin increased in the early twentieth century. The new practice resulted in a remarkable case of 'reagroforestation' of a slash-and-burn landscape (Michon *et al.*, 2000). Dipterocarp trees are considered difficult to regenerate but are successfully planted by the local farmers in slash-and-burn plots with rice, coffee (*C. canephora*), pepper (*Piper nigrum*), and fruit trees. The coffee is cultivated for 8 years, and then the damar and fruit trees grow together with natural regrowth. Resin tapping begins after 20–25 years and after 40–50 years, when the agroforests reach their full production. Dead trees are replaced under the canopy, but there is usually no replanting of the whole plot. Although most of the large trees in mature agroforests are damar trees, these are associated with many other useful tree species such as durian (*D. zibethinus*) and timber trees. The large durian trees that produce a popular and commercially important fruit as well as timber are also a common or dominant component of other types of Indonesian agroforests, sometimes with other fruit and various spice trees in the lower strata (Michon, 2005). In a comparison of rubber, damar, and durian agroforests in Sumatra, Thiollay (1995) found that damar agroforests were structurally most similar to primary forest with an often continuous canopy of 35–45 m height. The canopy of rubber agroforests was lower (20–30 m) and their understorey denser than that of the damar agroforests. Durian agroforests had a more open canopy at 30–45 m height composed of durian and other fruit and timber trees and a lower stratum of smaller trees such as clove (*Syzygium aromaticum*), cinnamon (*Cinnamomum* sp.), nutmeg (*Myristica fragrans*), and coffee (**Figure 6**).

The benzoin (*Styrax parallelloneurum*) agroforests in the highlands of northern Sumatra, Indonesia, are another intermediate subtype of CMSAF that are rotational but do not involve clearfelling. They are established by planting benzoin seedlings in the understorey of thinned primary or secondary forest. These seedlings eventually become tall trees growing in a matrix of remnant forest trees and forest regeneration. Tapping of the fragrant benzoin resin starts after approximately 8 years and can continue for 60 years, although yields decrease after 30 years. When tapping and the associated management of the ground vegetation are discontinued, the site reverts gradually into forest and the cycle can recommence several decades later. Benzoin rotations involving a slash-and-burn phase with rice cultivation are also known from Sumatra and Laos (Michon, 2005).

Intensively Managed Mixed Systems

In the CMSAF discussed so far, tree crops are associated with a substantial amount of spontaneous vegetation, some of it valuable and retained on purpose or even nursed, whereas some are merely tolerated, reflecting a strategy of low management intensity and temporary abandonment. Spontaneous vegetation often dominates in the less intensively managed strata: the shade canopy where the main commercial species are understorey crops or the lower and middle strata where the main commercial species are tall trees. Economically, these systems may be highly focused on a single, dominant tree crop species, even if they have high species diversity from a biological point of view.

However, high species and structural diversity can also result from intensive management, usually of relatively small plots, as in the case of tropical homegardens, where CMSAF are built largely from planted species. Homegardens have been defined as "intimate, multistorey combinations of various trees and crops, sometimes in association with domestic animals, around homesteads" (Kumar and Nair, 2004). Although individual homegardens are typically small, they can occupy significant areas in densely settled regions. For example, 20% of the arable land in the island of Java, Indonesia, has been estimated to be under homegarden use, and the state of Kerala in India has approximately 5.4 million homegardens, both densely populated areas with more than 800 people per square kilometre. Homegardens have a tradition dating back several thousand years in both regions. Although homegardens have been studied more frequently in Asia, they are also common in

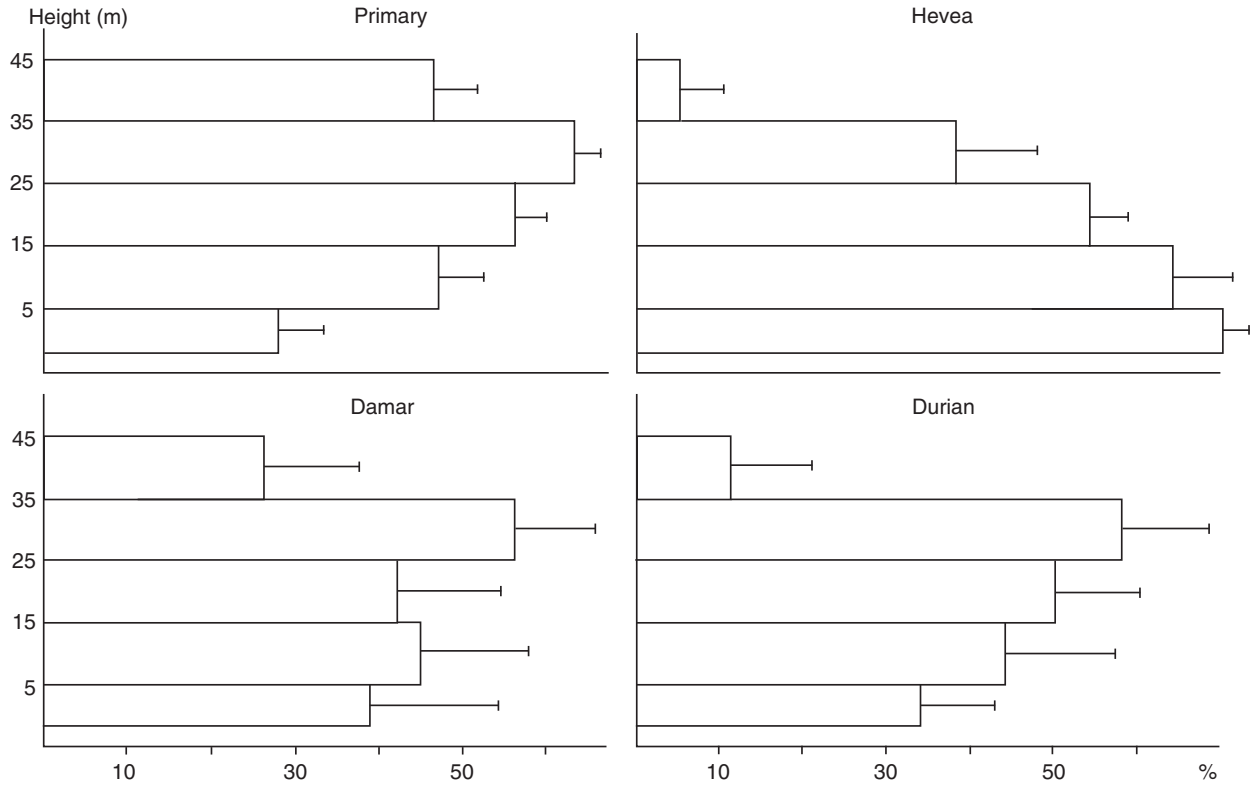

Figure 6 Height profiles of mean foliage cover in primary forest and agroforests based on rubber, damar, and durian in Sumatra. In: Schroth, G., *et al.* (Eds.), Agroforestry and Biodiversity Conservation in Tropical Landscapes. Island Press, Washington, DC, pp. 227–260 and Thiollay, J.-M., 1995. The role of traditional agroforests in the conservation of rain forest bird diversity in Sumatra. Conservation Biology 9, 335–353.

Africa, Central America, and the Amazon. In the Amazon, homegardens are common on anthropogenic Dark Earths and may have been sites of early plant domestication by Amerindians (Fraser *et al.*, 2010). The number of species in individual homegardens can range from a few to more than 70, and the homegardens of West Java collectively harbor more than 600 species, although some varieties have reportedly been lost over the past few decades (Kumar and Nair, 2004). The transition from homegardens to other crop fields or more extensively managed CMSAF is often gradual. For example, in the Tapajós region of the Brazilian Amazon, there is often a gradual transition from clean-weeded, homegarden-like systems composed essentially of planted species, such as rubber trees, cupuaçu trees (*Theobroma grandiflorum*), and açai palms (*Euterpe oleracea*) in the proximity of the homestead, to extensively managed, secondary forest-like rubber agroforests at greater distance from the communities (Schroth *et al.*, 2003, **Figure 5**). Homegardens can contribute significantly to household food needs, especially of fruits and vegetables and during lean times, although they are usually complemented by annual crop fields in the farming system. Homegardens can also be significant sources of timber, fuelwood, and a range of nontimber products including medicine, as well as animal products such as milk and eggs, and generate cash through the sale of part of their production (Kumar and Nair, 2004).

Forest-Enrichment Systems

Homegardens represent the intensive end of CMSAF, characterized by a dominance of cultivated species, whereas forest-enrichment systems are the extensive end and transition into extractively used natural forests (wild harvesting). In these systems, useful plants are integrated into more or less disturbed natural forest, for example, in clearings or along water courses, but in contrast to the systems discussed earlier, the natural forest vegetation remains dominant. Hunter-gatherers in the Amazon appear to have enriched forest around campsites with useful palms and other trees for several thousand years (Politis, 2001), which is similar to the practice in Indonesia, whereas the transfer of forest species to areas around campsites was an early form of plant domestication (Michon and de Foresta, 1999). More recent practices in the Amazon include the sowing of açai palms in riparian forests (Schroth and da Mota, 2007, **Figure 7**) or the enrichment of natural rubber groves with rubber seeds or seedlings to counteract the decline of the tapped mature trees (Dean, 1987). The planting of clusters of rattan palms into thinned forest can be found in Kalimantan, Indonesia (Michon, 2005). If natural forest with high densities of useful trees whose regeneration was facilitated by human disturbance were included in the concept of CMSAF, then this would reportedly be applied to some 11% of the Brazilian Amazon, where such human-modified forests are

(Eds.), Farming with Nature – the Science and Practice of Ecoagriculture. Island Press, Washington, pp. 103–120.

thought to prevail (Scoles and Gribel, 2011). Examples include the oligarchic forests dominated by açai palms – in fact transitional systems between extractivism and agroforestry – in the Amazon estuary (Muniz-Miret *et al.*, 1996); forest fallows with high densities of tucumã palms (*Astrocaryum tucuma* syn. *Astrocaryum aculeatum*) that produce valuable fruits in the central Amazon (Schroth *et al.*, 2004a); and probably forests with high density of Brazil nut trees (Scoles and Gribel, 2011).

Environmental Functions

The environmental functions of CMSAF have mostly been studied at the scale of the plot or farm and with a short-term focus, but ultimately to determine their true relevance to global environmental issues, they need to be considered at the scale of the landscape and over timescales of years or decades. In view of the ongoing forest loss in many tropical countries, of particular interest is whether CMSAF replace forest or help conserve forest, or even help to restore forest functions where these have previously been lost. From an environmental point of view, especially in view of global climate change and biodiversity loss, the replacement of primary or advanced secondary forest by tree crops, even if managed as CMSAF, is much less desirable than the sustainable intensification of existing agroforests (see Section Production and Intensification) and their expansion on already cleared agricultural or fallow land. Where the conversion of native forest is inevitable, the efficient and sustainable use of the cleared land is paramount (Schroth *et al.*, 2011a). Unfortunately, some tree crops such as cocoa have a history of often being planted as pioneer crops on recently cleared forest land where soils are fertile, weed and pest pressures low, and the microclimate favorable, although the sustainable management, intensification, and replanting of existing farms have been neglected (Gockowski and Sonwa, 2011; Ruf and Schroth, 2004). When remnant trees were retained or allowed to regenerate in such systems, outstanding examples of CMSAF such as the cabrucas of Brazil, the cocoa agroforests of southern Cameroon, or the coffee agroforests of Kodagu, India, have resulted, but at the cost of forest conversion. A major environmental achievement of these CMSAF that were built from standing forest is to have conserved more of the forest cover and functions than would have been possible if forest had been converted into simpler agricultural systems. For example, the fact that Brazil's main cocoa production region in southern Bahia, one of the most biodiversity-rich parts of the Atlantic Forest Biome, is still largely forested and enjoys high levels of species conservation despite the fact that natural forest has been reduced to less than 10% of its original extent is due to the dominance of cocoa agroforests in the agricultural landscape (Schroth *et al.*, 2011b). Despite these favorable environmental characteristics of shaded tree crop systems, the conversion of forest into CMSAF should only be considered where options of replanting and intensification on existing agricultural land have been exhausted.

However, where CMSAF are built by restoring agroforest vegetation on previously cleared agricultural or even savannah land, the environmental benefits are unambiguous. Indonesian and Amazonian rubber agroforests are examples of CMSAF that replaced natural forest fallow in slash-and-burn systems. Although these agroforests are eventually cleared and replanted, this happens at relatively long time intervals and would also happen with normal forest fallows. It has been shown that the expansion of rubber agroforests in Borneo occurred at the expense of secondary rather than primary forest, and as a consequence the total area of secondary and agroforest cover (including rubber agroforests) may have locally increased (de Jong, 2001). Rubber agroforests in Sumatra, however, seem to have expanded during the twentieth century at the expense of primary forest (Feintrenie and Levang, 2009). Permanent agroforests that are planted on agricultural land but require no subsequent slash-and-burn events for replanting, as in the case of damar agroforests in southern Sumatra, are another environmental quantum leap in the reagroforestation of agricultural land. Because the continuous regeneration of damar trees imposes no age restriction on these agroforests, their structure approaches that of primary forest even more closely than that of rotational forms of CMSAF does (**Figure 6**); moreover, their biodiversity value is very significant (Michon and de Foresta, 1999). However, in the absence of effective forest conservation measures, such

permanent agroforests can also expand into forest land and thus indirectly help natural forest loss as agricultural land becomes scarce (Kusters *et al.*, 2008).

Ecological significance is also associated with cases where farmers have used agroforestry practices in savannah areas to create CMSAF by planting tree crops that usually pertain to a forest environment, thereby effectively expanding the forest domain. One such case was described from the forest–savannah transition zone of central Cameroon, where farmers progressively established multilayered systems of food and tree crops on savannah land to suppress competitive grasses, and then inserted cocoa seedlings in the understorey. Subsequent increases in soil carbon contents showed the power of trees to restore soil fertility (Jagoret *et al.*, 2012). Other examples of the 'agroforestation' of savannah land include coffee agroforests around villages in Guinea (Correia *et al.*, 2010).

Although not as good as natural forest, there is now an increasing body of research demonstrating the value of CMSAF for biodiversity conservation where they can be a valuable complement for natural forest and very much better than agricultural monocultures. Although all agroforests are somehow disturbed and therefore unable to harbor certain sensitive forest specialist species, the value of agroforest habitat for many rare and endangered species that would not be able to survive in open agricultural landscapes is firmly established (Cassano *et al.*, 2009; Estrada *et al.*, 2012; Schroth *et al.*, 2004c). Agroforests are also often used by forest species as movement corridors (**Figure 8**). Many authors have, however, stressed the need to conserve forest remnants even in landscapes with high agroforest cover in order to conserve the full suite of native species (Faria *et al.*, 2007; Schroth and Harvey, 2007; Schroth *et al.*, 2004c).

Other environmental functions of these land use systems have less often been quantified. Owing to the presence of large trees, CMSAF have higher carbon stocks in the vegetation than fields of annual crops and generally more than most other agroforestry systems. For example, in the cocoa agroforests of southern Cameroon, a total biomass of 304 Mg ha^{-1} has been measured, 56% of the biomass of primary forest (541 Mg ha^{-1}) at that site, whereas food crop fields only had 85 Mg ha^{-1}, or 16% of the biomass of primary forest (Duguma *et al.*, 2001). Because aboveground carbon stocks are concentrated in large trees, they should be highest in farms that retain large remnant forest trees soon after clearing and should decrease as these forest trees die or are sold off. The conservation and regeneration of large forest trees in CMSAF is thus an important measure for conserving the carbon stocks (and also the biodiversity) of agroforests. In a global review of carbon stocks in coffee production systems, Méndez *et al.* (2012) found average carbon stocks in the vegetation decreasing in the sequence: traditional coffee polycultures that contained large forest trees > commercial polycultures that associate coffee with a range of fruit trees > coffee monocultures with a simple shade stratum of legume trees > unshaded coffee monocultures. Belowground C stocks of tree crops are often approximately 20–30% of aboveground C stocks but can vary considerably and reach values of 1 and higher for species that are often pruned, for example, for the extraction of hearts of palm (Schroth *et al.*, 2002). When farms are very extensively managed or even temporarily abandoned, tree cover and presumably their biomass per hectare can increase. For example, an increase in tree density (and presumably carbon stocks) has been found by recent inventories in cocoa agroforests in southern Bahia, Brazil, compared with inventories carried out in the 1960s. This has been interpreted as an effect of the cocoa crisis and reduced management intensity of the past 20 years (Sambuichi *et al.*, 2012). Such increases may, however, be temporary and be lost when conditions improve and farm management intensifies.

Figure 8 Sumatran orangutan visiting a durian (*D. zibethinus*) tree in a rubber agroforest several kilometers from the nearest natural forest in Batang Toru, North Sumatra. (Photo: Schroth, G., unpublished)

In permanent agroforests that were established on slash-and-burn plots, total system biomass should increase over time approaching that of natural forest, although probably never reaching it owing to the absence of very large trees that can take several hundred years to grow. In rotational systems, such as certain rubber and rattan agroforests, however, the system biomass is periodically 'reset' through slashing, burning, and replanting and is best characterized through a time average, similar to that of monocyclic forest plantations. In Indonesia, Hairiah *et al.* (2001) reported carbon stocks of 89 Mg ha^{-1} in old rubber agroforest and a time average of 46 Mg C ha^{-1} in a rubber agroforest cycle between two slash-and-burn events, compared with 306 Mg C ha^{-1} in primary forest. Schroth *et al.* (2011a) reported C stocks of 143 (SD = 63) Mg ha^{-1} for eight old rubber agroforests in Brazil; primary forest was not measured at that site.

As CMSAF often form the transition between more intensively managed agricultural land and natural forest, they may also contribute to the conservation of forest carbon stocks by reducing the use of fire at the agriculture–forest interface. For example, in northern Thailand, the presence of tea agroforests in watersheds has reportedly reduced the use of fire in the same watersheds for fear of affecting the valuable tea plantings if fire went out of control. It has also been suggested that the presence of rubber agroforests on forest boundaries in the Tapajós region of the Amazon may have protected forest edges by encouraging a more careful use of fire, to which rubber trees are very sensitive, in slash-and-burn plots (Schroth *et al.*, 2004c). Other edge effects that commonly contribute to tree mortality and the degradation of forest boundaries, such as

strong winds, have been shown to be mitigated by secondary forests growing on forest boundaries and the same would be expected from agroforests, but this has not been specifically demonstrated. Agroforests are also often used for hunting because of the presence of fruit trees that attract wildlife. However, it is not known whether this diverts hunting effort from the forest, thereby protecting forest fauna, or attracts forest fauna into agroforests where it is more vulnerable. The net effect may be site dependent (Wilkie and Lee, 2004).

Hydrological services of CMSAF have rarely been quantified, although Philpott *et al.* (2008) showed that, like natural forest, coffee agroforests in the Sierra Madre de Chiapas in southern Mexico reduced the average size of landslides in comparison with simpler structured agricultural systems (**Figure 9**). Because CMSAF very often occupy sloping lands above irrigated plots and villages in the valleys, it can be assumed that they play a considerable role in filtering water and regulating water flows, functionally expanding the forests higher up in the mountains. In a study in Sumatra, Verbist *et al.* (2010) showed that on sensitive volcanic soils, shade coffee systems had lower surface run-off and erosion rates than sun coffee systems, although they cautioned that much of the catchment sediment yield was derived from river banks, footpaths, and roads and was unrelated to farm practices.

An indirect but potentially very significant environmental service role of CMSAF is to make land use in protected areas (where these are inhabited), or their buffer zones, more sustainable. Especially in Latin America, inhabited protected areas, such as biosphere reserves, extractive reserves, sustainable development reserves, and indigenous lands, occupy millions of hectares. Although these areas usually have restrictions on the types of land use that are permitted, the practice of slash-and-burn agriculture and cattle pasture within protected areas is quite common. Especially where CMSAF are traditional forms of land use in these reserves, they can be environmentally and socially more sustainable alternatives to slash-and-burn agriculture and pasture. For example, in the biosphere reserves of the Sierra Madre de Chiapas, Mexico, coffee agroforests are an important land use activity, especially at higher elevations (Cortina-Villar *et al.*, 2012), whereas in the Tapajós-Arapiuns Extractive Reserve in the Brazilian Amazon, rubber agroforestry and a more recent adaptation, agroforests based on timber and nontimber trees, are alternatives to the production of cassava flour in slash-and-burn agriculture (Schroth *et al.*, 2011a; Schroth and da Mota, 2013). CMSAF may also have value for tourism, but apart from some bird-watching tourism in shade coffee farms mostly in northern Latin America, this potential has been little explored.

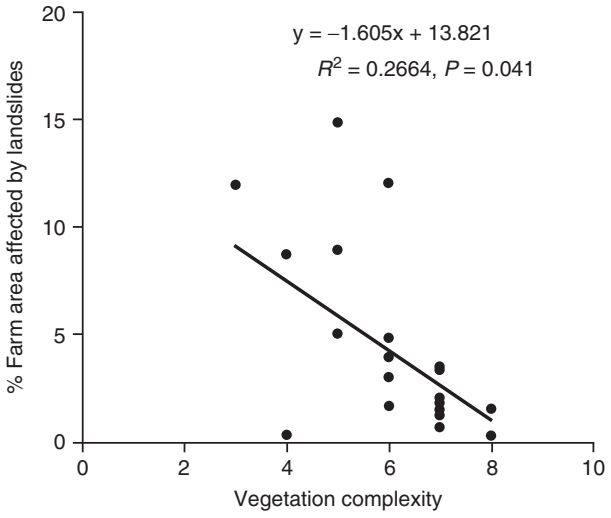

Figure 9 Percent coffee farm area affected by landslides as a function of vegetation complexity in coffee farms in the Sierra Madre de Chiapas, Mexico. Rustic and traditional polyculture farms have higher vegetation complexity scores (7–8), commercial polycultures mid-range scores (5–6), and coffee farms with simple shade have lower scores (3–4). Reproduced from (with kind permission from Springer Science and Business Media) Schroth, G., Läderach, P., Dempewolf, J., *et al.*, 2009. Towards a climate change adaptation strategy for coffee communities and ecosystems in the Sierra Madre de Chiapas, Mexico. Mitigation and Adaptation Strategies for Global Change 14, 605–625.

Production and Intensification

CMSAF are an important form of land use in many parts of the tropics. In Indonesia, a country with a long history and strong tradition in tree crop agroforestry, CMSAF has been estimated to occupy 6–8 million hectares, provide 80% of the rubber latex, 80% of dipterocarp resins, 95% of the benzoin, 60–75% of the main tree spices (clove, cinnamon, and nutmeg), and approximately 95% of the fruits and nuts, as well as significant quantities of bamboos, rattans, fuelwood, handicraft materials, and medicinal plants traded or used in the country (Michon, 2005). CMSAF are responsible for most of the cocoa area of southern Bahia, Brazil's main cocoa region, as well as 30% to 60% of cocoa farms in West and Central Africa, where most of the world's cocoa is produced (Gockowski and Sonwa, 2008). Despite the widespread simplification of shade canopies in recent decades, CMSAF are still an important form of coffee farming in Mesoamerica and the northern Andes, as well as Kodagu, from where 30% of India's coffee come (Garcia *et al.*, 2010). Homegardens provide a range of timber and nontimber (including food) products to millions of households throughout the tropics. For many farmers practicing CMSAF, these are their main source of income and products for domestic use, even if almost everywhere they are complemented by fields of food crops.

However, Michon (2005) stated that a weakness of complex agroforests in Indonesia is their apparently lower profitability compared with intensive production systems, and therefore, many of these traditional forms of CMSAF are under threat or even in the process of being replaced by more intensive land use forms such as monocultures of clonal rubber or oil palm. The same is true for other tropical regions. The rubber agroforests of the Tapajós, Brazilian Amazon, were probably always most typical of the river margins but have now lost any relevance on the flat plateau soils with the recent expansion of mechanized soybean agriculture (Schroth *et al.*, 2003). As mentioned before, Ruf (2011) observed a trend of progressive replacement of shaded cocoa farms by little or unshaded cocoa farms in West Africa, whereas many homegardens in Kerala and elsewhere have been replaced by simple

tree crop plantings and have lost many species and varieties (Kumar and Nair, 2004). Significant traditional shade coffee areas in Mesoamerica, northern South America and the Caribbean have been lost through conversion into lightly or unshaded systems (Perfecto *et al.*, 1996). In Kodagu, India, traditionally high shade levels in coffee farms have been reduced with the introduction of irrigation and crop diversification (especially pepper) and farmers increasingly use exotic trees (*Grevillea robusta*) instead of diverse native trees for shade (Garcia *et al.*, 2010).

Michon (2005) suggested that the apparently low profitability of many Indonesian agroforests which leads to their replacement by simpler land use systems is in part due to their management for diversification rather than intensification. However, extensive management and consequently low productivity is also characteristic of many CMSAF that are not particularly diversified from an economic point of view but are dominated by a single crop species (e.g., rubber or cocoa). Apparently, CMSAF lose ground as market conditions encourage greater specialization and more intensive management of a single or small number of currently most profitable crops. This is what will be seen if rubber agroforests are replaced by monocultures of clonal rubber trees in Indonesia or if homegardens are replaced by coconut plantations in Kerala, India. Cultural and societal changes such as increased urbanization and changing food preferences, certainly, also play a role (Kumar and Nair, 2004). Agricultural policies have also for many years encouraged monoculture practices, such as the replacement of traditional shade coffee and cocoa systems with less shaded systems, although farmers have not always followed these recommendations (Johns, 1999).

Considering the fluctuations of commodity prices on international markets and the numerous environmental risks to which producers of tree crops are exposed, switching to monoculture practices may not always be in the best long-term interests of local farmers, who may not have the financial and technical means to engage in such drastic changes of their traditional land use systems. Ruf and Schroth (2013) present a series of case studies illustrating a current trend toward diversification among tree crop farmers in regions that had previously been dominated by a single (often pioneer) tree crop such as cocoa, coconut, or coffee. This trend is motivated in part by severe price shocks affecting commodities such as coffee and cocoa during the past two decades and in part by environmental pressures such as pests and diseases, declining soil fertility, and climate variability. This diversification may take place at the plot, farm, or landscape level and does not necessarily result in CMSAF, but suggests that interest in diversified farming systems is again on the rise, counteracting to some extent the overspecialization that was a hallmark of the Green Revolution.

Where CMSAF are in decline not because of their diversification but because of their low productivity and profitability, research is needed into ways to increase their output while still preserving essential elements of these traditional, site-adapted systems. The following examples are intended to illustrate that the conservation, intensification, and promotion of CMSAF are multidimensional tasks which need to consider the dynamics of markets and society, in addition to agronomic and ecological questions, without attempting to be exhaustive.

Williams *et al.* (2001) studied the possibility of introducing grafted rubber seedlings in canopy gaps of Indonesian rubber agroforests in order to progressively increase their productivity without incurring the costs of clearfelling and replanting of entire plots. Although based on a traditional practice, this system has limitations in so far as rubber trees are light demanding and the seedlings are exposed to various risks (including damage from pigs and monkeys) when growing in canopy gaps. Schroth *et al.* (2004d) sought to increase the productivity of rubber agroforests in the Amazon and found that although some seed-grown trees in these agroforests were surprisingly productive despite the infertile, sandy soil, and extensive management, most trees had low productivity (**Figure 10**). However, farmers seemed to be reluctant to use grafted rubber seedlings even where this technology was available on nearby commercial plantations and this was interpreted as a risk avoidance strategy. For farmers who wanted to plant rubber but did not have access to, or were reluctant to use, grafted seedlings, a possible solution of intermediate intensity was to plant seeds from productive trees at higher-than-normal density, test-tap them at the age of 1–2 years, and then eliminate those saplings that showed the lowest potential. An adaptation of the traditional agroforestry practice whereby timber and nontimber trees were planted in slash-and-burn plots instead of (or in addition to) rubber trees was adopted by several hundred families (Schroth *et al.*, 2011a; Schroth and da Mota, 2013). Very recently, interest in rubber has increased in the area with increased market prices for rubber supplemented by a government subsidy. The impacts on cultivation practices remain to be seen.

In most parts of the tropics, cocoa is produced in systems of relatively low productivity, including in CMSAF. Examples include the cabrucas of southern Bahia, Brazil, which was once the second largest cocoa producer in the world but production fell precipitously in the 1990s through a combination of economic recession and the introduction of the witches' broom fungus (*Moniliophthora perniciosa*) of cocoa from the Amazon to which extension services initially had no appropriate response. Today, average cocoa productivity levels are approximately 250–300 kg ha^{-1} (Midlej and Santos, 2012); there is lack of qualified labor, and farm owners are indebted and unable to raise capital to invest in their farms. Therefore, although more disease-resistant and productive cocoa varieties for replanting and grafting of the old farms are now available, the crisis perpetuates itself. Legal restrictions on the felling of native trees prevent to some extent land use change, but also complicate the management of shade canopies. The cabrucas are of high value for the conservation of the exceptional biodiversity of this part of the Atlantic Forest biome and are part of the local culture (Schroth *et al.*, 2011b). Their maintenance will require an increase in productivity and probably also the development of additional forms of revenue from this traditional land use practice.

Coffee-based CMSAF in the highlands of Mesoamerica and the Andes have long been under pressure from agricultural extension services that favored monoculture practices. Now they are increasingly under threat from global climate change because the quality of Arabica coffee, and thus its price, is sensitive to high temperature. In addition, parts of the region will become drier and may suffer from an increase in extreme

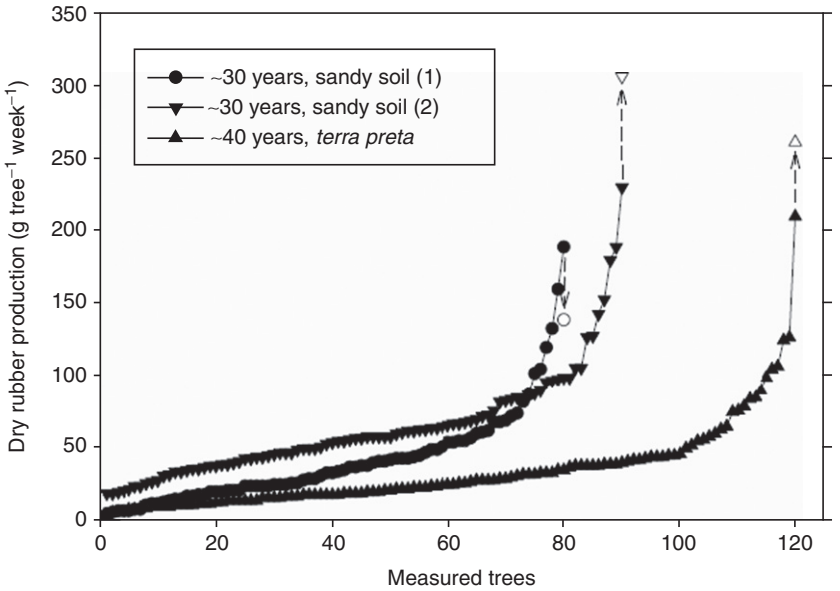

Figure 10 Productivity of individual rubber trees in three rubber agroforests in the Tapajós region of the Brazilian Amazon. Closed symbols show the productivity per tree at the beginning of the tapping season, and open symbols show the average productivity of the highest producing tree over the tapping season. Reproduced from (with kind permission from Elsevier) Schroth, G., Moraes, V.H.F., da Mota, M.S.S., 2004d. Increasing the profitability of traditional, planted rubber agroforests at the Tapajós river, Brazilian Amazon. Agriculture, Ecosystems and Environment 102, 319–339.

weather events such as hurricanes (Schroth *et al.*, 2009). A decrease of the profitability of coffee agroforests in areas such as the Sierra Madre de Chiapas, Mexico, might lead to their replacement with cattle pasture and consequently an increase in the use of fire, which has been a threat to the area's forests and coffee farms during drought years. Moreover, coffee agroforests have been shown to afford better protection against landslides than more simply structured land use forms (Philpott *et al.*, 2008). Increased diversification of the coffee farms with other tree crops has been among the recommendations to reduce the vulnerability of the farms to climate hazards (Schroth *et al.*, 2009), complemented by carbon trading and a government scheme of payments for environmental services to incentivize tree planting and forest conservation on the coffee farms and in the wider landscape (Cortina-Villar *et al.*, 2012; Schroth *et al.*, 2011a).

Although homegardens and similar types of agroforests have been early sites of tree domestication in several parts of the tropics, CMSAF are mostly made up of plants that have been relatively little improved through selection and breeding and therefore have relatively low and variable productivity. This is often true for the main crop species (e.g., cocoa or rubber planted from local seed) but even more so for secondary planted species and especially naturally grown species that were retained for their usefulness. One way to intensify cocoa CMSAF is to domesticate these 'companion trees' for the improved production of indigenous fruits and nuts (Leakey *et al.*, 2005). This approach is well advanced in Cameroon, where trees are selected for higher and more homogeneous productivity and greater product quality. It is being recognized as an important way to increase the incomes of rural communities (Leakey *et al.*, 2012). Likewise, Schroth *et al.* (2004a) have described a simple and low-cost management approach for improving the fruit quality and productivity of an Amazonian palm species, *A. aculeatum* syn. *A. tucuma*, that regenerates abundantly in disturbed sites (such as agroforests, crop fields, and fallows) but is very difficult to germinate and plant.

Futures of CMSAF

Change is normal in agricultural systems. Some CMSAF, such as homegardens, are thousands of years old and may have been sites of early plant domestication. Other CMSAF were invented by tropical farmers within the past hundred years, responding to an increased demand for commodities that extractive systems were not able to support or taking advantage of new crops and integrating them into their traditional land use systems. Some CMSAF reflect strategies of occupying land and taking it into production at relatively low cost, whereas others are carefully built and managed systems where a variety of crops occupy different ecological niches within a farming system. During the second half of the twentieth century, many CMSAF came under pressure from agronomists who favored intensive, monoculture production systems in the style of the Green Revolution. More recently, under the pressure of years of low commodity prices and increased risks from global climate change, the advantages to tropical farmers of producing several different outputs than depending on a single product has been more commonly recognized among farmers and agricultural policy makers (Ruf and Schroth, 2013). However, globalization and increasing global demands for commodities such as rubber and oil palm provide farmers with strong incentives to specialize and intensify their production systems, at least where inputs are affordable and markets and policies are

perceived as reliable. Changing availability of land and labor and changes in cultural norms also influence land use systems, but predicting these effects is not straightforward. Although the replacement of homegardens by simpler tree crop systems in Asia has been explained with a lack of labor to maintain them (Kumar and Nair, 2004), the same factor currently contributes to maintaining extensively managed cocoa agroforests in Brazil.

A novelty for the past 20 years is the increasing recognition of environmental services provided by land use systems such as CMSAF, including their biodiversity (Schroth *et al.*, 2004c). Certification systems such as 'Bird-friendly coffee' have been created to attract premiums and prevent the simplification of shade canopies that are used by resident and migratory birds, whereas shade coffee has been included in governmental and nongovernmental payments for environmental services programs in Mexico (Schroth *et al.*, 2011a) and Costa Rica. In some areas, CMSAF farms attract foreign tourists and Fair Trade premiums. In Brazil, legal restrictions on tree felling are a factor maintaining CMSAF besides increasing the cost and reducing the potential revenue from their management (sustainable or otherwise). However, government subsidies for tree products from the Amazon (such as rubber) are intended to benefit extractive systems but will also benefit CMSAF.

In view of these diverse forces, it is difficult to predict the future of CMSAF and most likely there will be different futures depending on region and type of practice. It is predicted that CMSAF have the best prospects to remain part of the landscape in areas where there are specific government policies for conserving land use practices of intermediate intensity, such as in inhabited protected areas (Cortina-Villar *et al.*, 2012; Schroth *et al.*, 2011a; Schroth and da Mota, 2013) and probably in a more intensively managed version in periurban areas with high demand for a range of fruits and other tree products. However, where environmental, market, and policy conditions are favorable for intensive agricultural production of single commodities, such as rubber or oil palm, CMSAF are likely to be replaced by more intensively managed monocultures.

Glossary

Agroforestry A managed land use that combines elements of agriculture and forestry, sometimes described as a two-tiered farming system.
Earthflow A downslope viscous flow of soil and rock material saturated with water under the pull of gravity. Earthflows are a shear above a failure plane in underlying rock. They can be deep flowing with the failure plane deeper than the rooting depth of trees.
Gully An eroding landform created by running water. Gullies in hill sides can be very large and difficult to stabilize, notably where the bedrock is exposed. Subterranean gullies are called tunnel gullies.
Loess A type of silty or loamy soil arising from wind deposition of the parent material, which because of its loose or uncompacted nature is very prone to rapid erosion, notably wind erosion.
Regolith The layer of loose material that sits atop bedrock. It includes soil and unconsolidated rock material.
Shallow landslide The downward falling or sliding of a mass of soil, often because of saturation with water. Shallow landsliding can be reduced substantially where soil is reinforced by tree roots.
Silvopastoralism A form of agroforestry where the agricultural element is pastoral farming; cf. arable farming.
Slump A collapse of the regolith initially triggered by some catastrophic event, for example, an earthquake, a flooded stream undermining the base of a hill slope, or an exceptional rainstorm. Initial rapid collapse is followed by slower ongoing movement often for several years.

Introduction

Soil is one of the most precious resources. The loss of soil, particularly through the land degradation processes of wind and water erosion, is one of the most serious environmental problems the world is faced with, as it reduces the means of producing food. Approximately 80% of the world's agricultural land was reported, almost 20 years ago, to suffer moderate to severe soil erosion and 10% to suffer slight to moderate erosion (Pimentel *et al.*, 1995). These statistics are unlikely to have improved since 1995, as farm sizes have increased, woody vegetative boundaries have been removed, and more sloping land has been brought into pastoral and arable cultivation to feed and fuel an increasing world population. Erosion rates on sloped arable land are of an order higher than rates on forested slopes (Cerdan *et al.*, 2010; Pimentel *et al.*, 1995). Land-use change following deforestation of sloped land is generally from forest to arable agriculture, with its accelerated risk of soil erosion. The negative effects of soil erosion include water pollution and siltation, crop yield depression, organic matter loss, and reduction in water storage capacity (e.g., Pimentel *et al.*, 1995; Bakker *et al.*, 2004; Cerdan *et al.*, 2004; Boardman and Poesen, 2006), which may lead to fundamental social challenges, such as land abandonment and the decline of rural communities (Bakker *et al.* 2005).

Water and Wind Erosion

Water erosion is the removal of soil by water and transportation of the eroded materials away from the point of removal. Water action due to rain erodes the soil and causes activities like gully, rill, and stream erosion leading to the downstream effects of flooding and sedimentation. The severity of water erosion is influenced by slope, soil type, soil water storage capacity, nature of the underlying rock, vegetation cover, and rainfall intensity and period.

Wind erosion is caused by the action of the wind on the soil surface and is the process by which fine soil particles are carried away. Wind erosion is a serious problem in many parts of the world, especially in arid and semiarid regions. It affects agricultural land in much of Northern Africa and the Near East; parts of Southern, Central, and Eastern Asia; Australia; Northwest China; Southern South America; and North America.

The severity of wind erosion is influenced by wind speed, the condition of the soil surface, and the amount of vegetation cover present. Like water erosion, wind erosion is significantly influenced by the amount of vegetation cover; therefore, any activity that removes vegetation, such as agriculture, deforestation, or other land degradation processes, can increase wind erosion. Wind erosion creates problems far from the initiation point with dust storms reducing air quality in urban areas and in adjoining countries in some cases.

Factors Contributing to Erosion Risk

Increased risk of erosion and sediment shift is associated with high soil erodibility; little ground cover; steep, long, and continuous slopes; high intensity storms; high drainage density of the slope; and proximity to natural waterways. Planting vegetation is one of the most effective and cost-saving strategies of reducing soil erosion, particularly on slopes. Trees

 doi:10.1016/B978-0-444-52512-3.00247-3

have the capability through their root architecture, protective canopy, ability to divert and disrupt air flow, and reshaping of the landscape to reduce the erosion of soil from vulnerable landscapes.

Agroforestry as a Technology to Reduce Soil Erosion on Agricultural Land

Agroforestry and silvopastoralism are promoted as technologies that include trees in an arable or pastoral farming system to add economic value to the farming operation. Reduction of soil erosion can be a significant consequence of developing such two-tiered farming systems, particularly where the region is prone to high wind run or heavy rainfall and where the soils are thin and are easily transported by wind or water. Deforestation and overgrazing have been identified as significant contributors to soil loss in many regions of the world, and the replacement or planting of trees has become a high priority for the retention of soil on slopes or where wind erosion is causing significant soil loss.

The combination of trees and agriculture in the temperate region has become less common in modern agricultural practice, as the trees have been viewed as an impediment to intensifying agriculture (Tsonkova *et al.*, 2012). However, the increased knowledge of negative consequences originating from conventional agriculture, for example, soil erosion, water pollution, and biodiversity loss, has restored the interest in agroforestry practices within many regions of the world (Reisner *et al.*, 2007). The challenge facing the adoption of agroforestry practices is whether they will provide the same economic outcomes as conventional agriculture. This is equally true in temperate and tropical agricultural systems (Abdi *et al.*, 2013; Meena *et al.*, 2012). Ecological outcomes through prevention of soil erosion are often not considered significant enough to introduce a silvopastoral or agroforestry component to agricultural systems. Deforestation has generally been carried out to develop pastoral or arable land to feed communities and improve the local economy, to source lumber, or to open up the land for mining (Kusimi, 2008). Consequently, the economic value of afforestation must match the economic value of the land, without trees, for agriculture. Trees provide fuel, fodder, and timber, and uptake of agroforestry increases where this providence is important to the landowners. In the present context of reducing soil erosion on agricultural land a number of examples demonstrate the efficacy of this approach. The forest soils of San Pedro Mixtepec, Oaxaca, Mexico became prone to water erosion following the loss of plant coverage. This was due to opening of sloped lands to cultivation and overgrazing in lands with slopes $>27^{\circ}$. The establishment of an agroforestry system with *Leucaena leucocephala* (Lam.) de Wit and *Moringa oleiferous* (Lam.) in terraces reduced removal of soil by water erosion from 16.67 to 2.17 Mg ha^{-1} $year^{-1}$, compared with unprotected slopes (Sanchez-Bernal *et al.*, 2013). The same trend was reported by Saha *et al.* (2011) in Northeast India following the introduction of agroforestry to shifting cultivation practices.

Sourabh *et al.* (2013) observed that retention of trees were included in a variety of technological innovations used by indigenous communities in Northeast India for making the system more productive, less degradative, and able to generate cash income for modern living. Agroforestry is one of the preferred land-use options for smallholder farms in the Philippines due to its ability to increase land productivity and protect soil from erosion (Delgado and Canters, 2012). Their modeled predicted soil loss showed higher risks on sloped lands under nonagroforestry use.

Widespread erosion and landslides following rapid conversion of sloping lands in Democratic People's Republic of Korea, in association with heavy rainfall events, have led to the promotion of agroforestry at a policy level to conserve soil. Timber (*Larix leptolepis*) and fruit (aronia berry: *Aronia melanocarpa*) trees are the preferred options planted as contour strips (Xu *et al.*, 2012). Meena *et al.* (2012) stressed the importance of the economic benefits, additional to soil conservation, of agroforestry in the semiarid and arid regions of Northern India, if there were to be uptake of the technology. Technical advice on management of trees for the maintenance of pasture and for saleable products was identified as a key factor. The delayed economic benefits of trees planted for erosion control is a sufficient barrier to agroforestry in some rural societies (e.g., Jos Plateau, Nigeria, see Thapa and Yila, 2012). To expedite the wider adoption of these technologies and to halt and reverse soil degradation, it is suggested that farmers initially be supported with economic incentives to compensate their short-term economic loss (Das and Bauer, 2012).

Using Trees to Manage Mass Movement Erosion Forms on Agricultural Land

The water-driven erosion forms discussed below are illustrated using examples and management strategies used for pastoral agrosystems in New Zealand. The two most suitable conservation tree species used for soil erosion management in New Zealand are poplar (*Populus* spp.) and willow (*Salix* spp.). The use of trees in pastoral agrosystems is best described as silvopastoralism.

Shallow Landslide Erosion

Shallow landslides, referred to as slips below, are the rapid flowing or sliding movements of soil and regolith exposing a slip surface. These can be shallow and parallel to the surface or deeper and more concave. They are caused by water infiltrating into the soil until it meets an impermeable layer when it flows downslope. Sufficient hydraulic pressure lifts the soil and turf mat, which then flows/slides downslope creating a debris tail over pasture, sometimes reaching the valley bottom or the stream (**Figure 1(a)**). Slips occur on a variety of rock types ranging from sandstones to mudstones and in loess deposited over hard rocks, such as limestone.

Studies have shown that following slippage, production on the eroded surface will only recover to approximately 80% of the uneroded surface (e.g., Rosser and Ross, 2011). It is, therefore, important from an economic perspective for farmers to minimize this loss of productivity.

To prevent the slip occurring, willow or poplar poles (vegetative cuttings, 2–3 m long) are planted up to 18 m apart

(a) (b)

Figure 1 (a) Severe slipping on soft mudstone in eastern North Island, New Zealand. (b) Young space planted willows reducing the risk of further erosion on an unstable slope. Photos McIvor, I.

across the slope in a regular pattern or, more usually, where the slipping is considered most likely to occur (Figure 1(b)). Slip-prone soils are often shallow and exposed to climatic extremes. The recommended practice is to plant a mix of clones, protect the new poles with sleeves, and actively manage them (e.g., replace dead trees and no cattle exposure for 2–3 years) for the first 5 years of growth to insure that a healthy tree develops. Where the potential for slip erosion is very severe to extreme, a closed canopy tree cover is recommended. However, this requires permanent retirement from pasture, a change many farmers are not willing to undertake.

Earthflow Erosion

Earthflow is a flow of soil and underlying regolith, generally characterized by retention of a pastured cover and often broken by tension cracks and smaller secondary movements. Such flows do not result in a separate slip scar and debris. Earthflows range from shallow to deep (1 to >70 m), from fast-moving to a very slow and discontinuous creep, and from retaining a continuous turf mat to having a broken surface with secondary movements. They may even have gullies cutting through them, increasing their instability. Earthflows move when the whole regolith is wetted up and the frictional resistance is at a minimum. This is generally later in winter and not usually in response to intense rainstorms.

The control measures applied depend on the type of earthflow. The measures rely on removing surface water to minimize infiltration by surface smoothing and constructing diversion banks, tying together the surface with willow roots, pair planting willows where gullies are most likely to form, and planting at the toe of the movement to hold up the toe (essential when the toe is being undercut by a waterway).

Both poplars and willows are used for managing earthflows (Figures 2 and 3). Willows are preferable to poplars for halting earthflows, as their roots form thick mats when in a wet environment. This holds the poorly structured mudstone better than poplar roots, which do not have this matting characteristic.

The willows are planted across the flow in a regular pattern at 8–15 m spacing. The regular pattern allows cultivation between the rows if any breakouts occur or for pasture renewal. As with poplars, silviculture is necessary to create an appropriate form and to reduce shading.

Slump Erosion

Slump erosion occurs where there is a backward rotation of a significant area of land. This erosion type is relatively uncommon, as most occur as a secondary feature following a flow or large slip leaving an exposed headwall which then collapses with a backward tilt. Slump erosion events are usually sufficiently large (Figure 4) that tree planting alone cannot control them. They need to have surface dam water drained the surface smoothed, and the area retired and close planted in trees. Once in trees, the slumps need to be closely managed, as continuing movement overturns or topples trees requiring clearing to keep drainage open and replanting. Over time movement reduces.

Fluvial Erosion Forms

Fluvial erosion occurs where the soil or regolith is exposed to running water, resulting in tunnel gully erosion or gully erosion.

Tunnel Gully Erosion

Tunnel gully erosion is an insidious process where subsurface soil layers are removed by water. The water moves down through the soil profile until it reaches a less permeable layer where it concentrates to flow downslope removing soil particles in its path and forming tunnel. These tunnels either partially or totally collapse over time. They occur in a wide variety of hill country environments ranging from strongly

(a) (b)

Figure 2 (a) Mudstone earthflow on pastoral land with protected poplar poles space planted to control the movement and (b) shallow earthflow on mudstone with movement halted by successful poplar planting. Photos Eyles, G.

weathered claystone, siltstone, and loessial hill country to uncemented ignimbrites.

Where climate allows and trees can grow, tunnel gullies can be controlled by planting a poplar or willow pole in the collapsed tunnels. The tree roots hold up the sediment gradually filling up the holes. Tunnel erosion is managed by identifying the characteristic sunken drainage lines and planting poles in these. In this way the tunnels fill up with sediment before any collapses (Figure 5).

Gully Erosion

Gully erosion (Figure 6) occurs where concentrated surface water scour out the regolith and underlying rock with the debris being either deposited downslope or transported into river systems creating major downstream problems. The gully

form and severity is very dependent on the rock type. The very severe to extreme gully erosion is restricted to argillites (crushed), mudstone, and fine siltstones with each rock type having its characteristic gully shape.

Prevention is much more effective than repair as once the erosion is into the bedrock it is very difficult to get trees (or any other plant material) established. The large gullies cannot be repaired. The whole catchment needs to be retired from grazing and planted in closed canopy trees with the eroding surfaces repeatedly planted with willow wands to create a vegetated surface. These sites take many generations before they are repaired.

The construction of debris dams (Lancaster and Grant, 2006) at intervals up the gully coupled with pair planting of willows has successfully controlled erosion from small gullies.

Figure 6 This gully formed overnight in 1900-year-old uncemented ignimbrite west of Taupo, New Zealand. In this environment, as an erosion prevention measure all drainage lines in pastured hill country are pair planted with tree willows at 15–20 m spacing and measures taken to insure the grassed surface is not broken, so allowing a gully head to form. Terrace edges need to be protected and either grassed waterways developed or flumes constructed.

The willow root mats grow across the gully bed and over the surface of the dam covering and protecting the eroding surface (Figure 7(b)). Tree pairs are spaced from 8 to 15 m up the gully depending on severity. Discontinuous gullies (Figure 7 (a)) are very common in hill country. Large erosion events fill the valley bottoms and smaller events begin to scour them. Prevention is by pair or single planting of willows up the valley bottom at 15–20 m spacing and at weak points developing a planted block with 2–3 rows of willows planted at 1.5 m spacing across the valley bottom and in an area fenced out from grazing.

Rill Erosion

Pasture renewal in easy hill country is often on a 5 to 10 year cycle involving desiccation of the existing pasture followed by surface disking, planting of a fodder crop, and then oversowing with an improved pasture spp. mix. Rill erosion when the surface is exposed can lead to severe soil loss (Figure 8).

Figure 8 Rill erosion on hill country cultivated for pasture renewal. Zero tillage techniques or strip cultivation will reduce the risk of soil loss. Photo Eyles, G.

(a) (b)

Figure 7 (a) A discontinuous gully and (b) gully control achieved by stabilizing the base level through construction of debris dams supported by willows. Note the willow root mat grown over the dam structure. Photos G. Eyles.

The risk of this is best minimized by zero or minimum tillage management systems that do not put the soil at risk. If cultivation is required, strip cultivation leaving grassed strips each 20 m on the contour across the slope will reduce the risk.

Stream Bank Erosion

In hill country, storm events can create flash floods in streams that scour out the side walls, deepen the profile, and cause gullies to form. This can be avoided by planting willows along the banks (Figure 9). The roots stabilize the banks and protect the stream floor from degrading.

Using Trees to Reduce Soil Loss from Wind Erosion

Wind erosion is a significant source of soil loss in many parts of the world (Figure 10) and its contribution to desertification and the loss of productive farmland is of international concern. Although wind erosion has been documented in China for centuries, in recent years the climate in these areas has become drier and as a consequence the problem has been getting worse (Shi *et al.*, 2004). Windbreak forest belts in desert areas in China are being used to effectively control soil erosion (Figure 11) and promote accumulation of organic matter and clay in the soil and formation of crust at soil surface, thus fixing drifting sands and accelerating formation of eolian sandy soil (Li *et al.*, 2012). Su *et al.* (2010) reported that shelterbelts of *Populus gansuensis* increased soil organic carbon by 14.6 times and 17.0 times after 7 and 32 years, respectively, compared with unprotected shifting sand land. Large shelterbelt schemes cover more than 11 million ha of wind erosion-prone land.

Windbreaks are one of the oldest agroforestry systems in North America. In the Canadian prairies, more than 43 000 km of windbreaks have been planted since 1937, protecting 700 000 ha. These windbreak plantings were initiated in response to large-scale generation of dust storms in the Dust Bowl during the 1930s. New policies and practices were

Figure 10 Tree roots exposed by erosive removal of soil by wind.

developed to conserve soil and livelihoods, in which windbreaks were a key component. In 1987, approximately 858 000 windbreaks in the United States, mostly in the north central and Great Plains areas, spanned 281 000 km and protected 546 000 ha (Williams *et al.*, 1997). Agroforestry approaches to combating wind erosion and desertification have been reported for Egypt (El-Flah, 2009), the Sudan (Dafa-Alla and Al-Amin, 2011), and Pakistan (Akram *et al.*, 2006), with varying degrees of success.

National Policy and Erosion-Control Practices

Erosion-control practices are reported from most countries where soil erosion in agrosystems occurs. Many of these practices are reported at an experimental level. Uptake of new technologies continues to be a challenge, particularly where the present economic situation of the landowner is at risk. Policies applied at a national or regional level often require financial incentives for uptake of the technology or practice. For farmers, soil loss is not necessarily equated with economic loss, because it can be offset by application of fertilizers or a change of crop.

The benefits of being able to apply national and regional policies on soil conservation and reduction of erosion as developed in the People's Republic of China are described in the next section. China has many examples of programs operating on a large scale that are highly successful in reducing wind- and water-induced soil erosion.

Illustrative Case Studies – China

Slope Erosion on Pastoral and Arable Land

Erosion is a prominent ecoenvironmental problem in China. The total land area suffering from water and wind erosion is 2 949 000 km^2, accounting for 30% of the national territory area (Table 1). The total area of territories suffering from water erosion is 1 293 000 km^2 and the total area of territories suffering from wind erosion hits 1 656 000 km^2. The west region of China experiences the most serious erosion, accounting for 80% of the total erosion area.

Table 1 Summary statistics of total erosion areas due to water and wind erosion

Types of soil erosion	*Degree of erosion*	*Area (10 000 km^2)*
Water erosion	Slight erosion	66.76
	Moderate erosion	35.14
	High erosion	16.87
	Severe erosion	7.63
	Extreme erosion	2.92
	Total	129.32
Wind erosion	Slight erosion	71.6
	Moderate erosion	21.74
	High erosion	21.82
	Severe erosion	22.04
	Extreme erosion	28.39
	Total	165.59

In China, soil and water erosion takes place mainly in eight regions. These regions have different geographical features, so they suffer different types of erosion (Table 2).

The black soil region of Northeastern China is very important to the soybean industry. Indeed, 45% of the soybean production in China is from this region. Although the restoration history of this region is shorter than that of other areas, accelerated erosion is known to be widespread across the black soil area. This widespread erosion has occurred because much of the cropland is located on long rolling slopes. Specifically, the black soil layer of black soil in the region has been reduced from 70–100 to 16–70 cm, and the level of soil organic matter has been reduced from 6% to 15% to 2% in the period from the 1950s to the 1980s. The accelerated erosion in this region led to a remarkable reduction in the effective soil depth. The Loess Plateau and upper reaches of the Yangtze and other rivers in Southwestern China suffer serious soil and water loss from slope farmland.

The Chinese government has enacted several laws and regulations for water and soil conservation, such as the provisional outline of soil and water conservation (1952), the act of soil and water conservation (1982), and the law of water and soil conservation (1991, 2010). During this time, the related departments and local governments have also established some regulations for water and soil conservation.

In the long term, water and soil conservation practices in China benefit from collecting together local experiences. The most important practice is comprehensive management of small watersheds. By the end of 2011, the total area of territories benefitting from water and soil conservation measures reached 992 000 km^2, among which 200 000 km^2 benefited from structural measures (terracing and silt retention dams), 779 000 km^2 from biological measures (afforestation, shelterbelts, and planting of shrubs and grasses), and 13 000 km^2 from other measures (tillage practices, restricting land use, and relocating population). A total of 58 446 silt retention dams have been built, with a silted land area of 928 km^2. Among them, 5655 backbone silt retention dams, with a storage capacity from 500 000 to 5 million m^3, provide a total storage capacity of 5.7 billion m^3. The producing and living conditions of the residents living in the work zones have become better. Approximately 150 million people benefit from the works of water and soil conservation and approximately 20 million poor people become richer.

Use of Conservation Trees in Erosion Prevention

Since these reforms and the opening up of policy, the Chinese government has launched several key forestry programs (Table 3). Simultaneously, other policies and regulations were promulgated. These key forestry programs greatly ease the ecoenvironmental problems of water and soil erosion in China. Five of these programs (Sloping Land Conversion Program, Three North Shelterbelt Program, Beijing–Tianjin Sand Storm Source Control Project, Loess Plateau Comprehensive Control Project, and Rocky Desertification Comprehensive Treatment Project) are focused on reducing water and soil erosion. The remaining programs also contribute to water and soil conservation; however, their main targets are other aspects of forestry.

Table 2 The main regions of China suffering from water and soil erosion

Region	*Geographical scope*	*Geographical features*	*Situation of erosion*
Black soil region of Northeastern China	• Heilongjiang • Jilin • Liaoning • Inner Mongolia	• Rolling hill regions with black soil • Downslope tillage	• Top soil loss
Mountainous region of Northern China	• Beijing • Hebei • Shangdong • Liaoning • Shanxi • Henan • Anhui	• Shallow soil • Bare rock • Steep slopes	• Easy to form torrential flood
Loess plateau	• Shanxi • Shaanxi • Gansu • Inner Mongolia • Ningxia • Henan • Henan	• Soil layer deep and loose • Ravines and gullies crisscross	• Soil erosion amount reaches to approximately 5000 t km^{-2} $year^{-1}$
Agropastoral interlaced region of Northern China	• Inner Mongolia • Hebei • Shaanxi • Ningxia • Gansu	• Excess land reclamation • Overgrazed	• Wind erosion and water erosion
Upper reaches of the Yangtze and other rivers in the Southwestern China	• Sichuan • Yunnan • Guizhou • Hubei • Chongqing • Shaanxi • Gansu • Tibet	• Complicated geological structure • Frequent geological activity • High mountains and steep slopes • Downslope tillage	• Mud-rock flow and landslips.
Karst region in Southwestern China	• Guizhou • Yunnan • Guangxi	• Unproductive soil • Bare rock • Steep slopes	• Rock desertification
Red soil regions of Southern China	• Jiangxi • Hunan • Fujian • Guangdong • Guangxi • Hainan	• Low mountain and hilly area • Broken topography • Steep slopes	• Slope disintegration
Steppe region of Western China	• Inner Mongolia • Shaanxi • Gansu • Qinghai • Ningxia • Xinjiang	• Excess land reclamation • Overgrazed	• Degradation and desertification of grassland

In China, the following six key forestry programs covered 97% of the counties of the whole nation.

The Natural Forest Protection Program covers the headwaters of the Yangtze River (the Three Gorges region as the boundary, including the provinces of Sichuan, Guizhou, Chongqing, Hubei, and Tibet), the Upper and Middle Yellow River (Xiaolangdi Reservoir as the boundary, including the provinces of Shaanxi, Gansu, Qinghai, Ningxia, Inner Mongolia, Shanxi, and Henan), and the state-owned forest area in Northeast of China (including the provinces of Jilin, Heilongjiang, Inner Mongolia, Hainan, and Xinjiang). Since the inception of the program 2.7 million ha of plantations have been established, 3.2 million ha of forests have been established by aerial seeding, 12 million ha of newly enclosed

Table 3 Key afforestation programs in China addressing soil and water erosion

Project name	*Project profile*
Sloping Land Conversion Program	● Duration: 1999–2010 ● Geographical scope: 25 Provinces and Xinjiang production and construction corps ● Relevant laws and regulations: Recommendations for Further Improving Sloping Land Conversion Policy (2002), The Regulations on Sloping Land Conversion (2002) ● Primary target: Solving the problem of water and soil erosion in key regions ● Present situation: From 1999 to 2011, the completed construction area covers 289 000 km^2, among which 92 000 km^2 from returning farmland to forest, 170 000 km^2 from afforestation in barren hills, and 27 000 km^2 from closed forest. The forest coverage in the construction area has undergone a 3% increase
Three North Shelterbelt Program	● Duration: 1978–2050 ● Geographical scope: 13 Provinces ● Relevant laws and regulations: Recommendations for Further Improving the construction of the three north shelterbelt system (2009) ● Primary target: Effectively controlling the hazards of sand storms and water and soil erosion. Constructing a shelter–forest network for fields in the plains ● Present situation: By the end of 2012, the total area of afforestation covered 265 000 km^2. The forest coverage in construction area now reaches 12.4% of the land area
Beijing–Tianjin Sand Storm Source Control Project	● Duration: 2001–10 ● Geographical scope: 5 Provinces ● Relevant laws and regulations: Project Planning of Beijing–Tianjin Sand Storm Source Control (2002) ● Primary target: Effectively controlling the desertification of the land ● Present situation: The forest coverage in construction area increased from 12.4% in 2000 to 18.2% in 2009
Loess Plateau Comprehensive Control Project	● Duration: 2010–30 ● Geographical scope: 7 Provinces ● Relevant laws and regulations: Planning of Loess Plateau Comprehensive Management (2010) ● Primary target: Controlling the water and soil erosion and reducing the quantity of sediment flowing into the Yellow river ● Present situation: The area of afforestation covers 78 000 km^2. The forest coverage in construction area increased from 11% in 1977 to 19.6% in 2012
Rocky Desertification Comprehensive Treatment Project	● Duration: 2008–15 ● Geographical scope: 8 Provinces ● Relevant laws and regulations: Planning of Rocky Desertification Comprehensive Treatment 2006–15 (2008) ● Primary target: Controlling and preventing the spread of stony deserts and water and soil erosion. Conversion of the slope land ● Present situation: By the end of 2011, the area of afforestation reached to 8000 km^2. The area of stone desertification reduced by 9600 km^2 from 2005 to 2011
Natural Forest Protection Program	● Duration: 1998–2020 ● Geographical scope: 17 Provinces ● Relevant laws and regulations: Implementation Plan of Natural Forest Protection in Upper Reaches of Yangtze River and Upper and Middle Yellow River (2000), Implementation Plan of Nature Forest Protection in the Key State-Owned Forest Areas in the Northeastern China and Inner Mongolia (2000) ● Primary target: Prohibiting the cutting of natural forest in upper reaches of the Yangtze River and upper and middle Yellow River. Reducing the forest harvest in the key state-owned forest areas in the Northeastern China and inner Mongolia ● Present situation: The forest coverage in construction area has a 3.7% increase
Plain Farmland Shelterbelts Program	● Duration: 1988–2020 ● Geographical scope: 26 Provinces ● Relevant laws and regulations: Greening Standard of Plain Counties In Northern and Central China (1987), Greening Standard of Plain Counties in Southern China (1987), Planning of Reaching Nation Standard in Greening the Plain Counties (1988), Program Planning of Plain Farmland Shelterbelt 2006–10 (2006)

(*Continued*)

Table 3 Continued

Project name	*Project profile*
	● Primary target: Perfect the plain farmland shelterbelt system and forest ecosystem. Greening along the highways, railways, and waterways. Improving the quality of the forest in plain area. Insure stable grain production ● Present situation: By the end of 2010, the area of afforestation reached 71 000 km^2. The forest coverage in construction area increased from 7.3% in 1987 to 15.8% in 2010
Yangtze River Basin Shelter Forest System Project	● Duration: 1989–2020 ● Geographical scope: 17 Provinces ● Relevant laws and regulations: First-Stage Project Planning of Yangtze River Basin Shelter Forest System Construction (1986), Second-Stage Project Planning of Yangtze River Basin Shelter Forest System Construction 2001–2010 (2000) ● Primary target: Improving the deteriorative ecoenvironment in the Yangtze River Basin ● Present situation: From 2002 to 2011, the area of afforestation reached to 11 700 km^2. By the end of 2011, the forest coverage in construction area reached to 45.4%
Sanjiangyuan Ecological Protection and Construction Project in Qinghai Province	● Duration: 2004–20 ● Geographical scope: Qinghai Province ● Relevant laws and regulations: Overall Planning of Ecological Protection and Construction in Sanjiangyuan (2005), Overall Development Scheme of Sanjiangyuan National Comprehensive Experimental Area of Ecological Protection in Qinghai Province (2011) ● Primary target: Improving the construction of ecological protection and infrastructure ● Present situation: The vegetation coverage had a 3.08% increase in construction area

nonforested land and open forest land has been set aside for natural regeneration, 101 million ha of forest has been taken into management and protection, and 621 500 foresters have been resettled in other locations.

The Shelterbelt Forest System Project covers the Northwest, Northeast, and the North of China; the middle and lower reaches of the Yangtze River; the coastal area; the Pearl River Basin; the Huai River Basin; Taihang Mountain area; and the plain area. By establishing farmland shelterbelt forest and planting trees on barren land, by the end of 2008, 24.5 million ha of forest had been conserved by the program and the forest coverage in the three northern regions had increased from 5.1% in 1978 to 10.5% in 2008. The program has overseen the improvement of 270 000 km^2 of sandy lands and the stabilization of 380 000 km^2 of water and soil erosion areas. Since 2000, the river basin programs within this project have collectively established 4.3 million ha of plantation.

The Sloping Land Conversion Program involves 25 provinces (Beijing, Tianjin, Hebei, Shanxi, Inner Mongolia, Liaoning, Jilin, Heilongjiang, Anhui, Jiangxi, Heinan, Hubei, Hunan, Guangxi, Hainan, Hongqing, Sichuan, Guizhou, Yunnan, Xizang, Shanxi, Gansu, Qinghai, Ningxia, and Xinjiang) and Xinjiang Production and Construction Corps. According to the principle of highlighting the key points, the upper reaches of the Yangtze River, the upper and middle reaches of the Yellow River, Beijing–Tianjin sand source district, critical lake watersheds, the Hongshui River Basin, the Hei River Basin, and the Tarim River Basin are the focal points of the program. This program began in 2000 after massive flooding was caused in part by land clearing and focuses on China's largest source of soil erosion and flood risk – arable farms on steep slopes. The program is a land retirement program that aims to reduce soil erosion by returning cropland on steep slopes back to forest or grassland. Farmers are recompensed for giving up farming this land. Between 2000 and 2009, 4.8% of the cropland had been converted into forest land in Guyuan, according to regional experts. In Ansai County, the implementation of the grain for green program increased the newly forested land substantially to 21.4% of the study area by 2010 at the cost of both cropland and shrub–grassland, which decreased by 46.3% and 18.8%, respectively, from 1995 to 2010. Consequently, the coverage of forested land (both older forest and newly forested land) increased from 12.4% in 1995 to 37.7% in 2010.

The Beijing–Tianjin Sand Storm Sources Control Project ranges from Damao Banner in Inner Mongolia in the west, Ar Horqin Banner in Inner Mongolia in the east, Dai County in Shanxi Province in the south, and East Ujimqin Banner in Inner Mongolia in the north, including Beijing, Tianjin, Hebei, Shanxi, and Inner Mongolia. This program was launched in 2001 and by the end of 2009, 8.2 million ha of desertified land had been treated through various means, including 5.3 million ha of afforestation, 2.0 million ha of grass establishment, and 784 000 ha of small water basin treatment at a cost of US$3.5 billion.

The Wildlife Protection and Nature Reserve Development Program involves eight regions, which are mountain and plains area in Northeast China, desert region in Mengxin Plateau, plain and Loess Plateau in North China, high-cold region in Qinghai–Tibet plateau, alpine and gorge region in Southwest China, hilly area in south central China, hilly and plain area in East China, and hilly area in South China. In 2010 there were 2349 nature reserves of various types in China, accounting for 15.2% of total land area, among which 1706 were managed by the forestry sector. The nature reserves established by the forestry sectors alone have put 90% of terrestrial ecosystem, 45% of natural wetland, 85% of wild animal populations, 65% of higher plant communities, and 20% of natural high-quality forest under effective protection.

Table 4 Tree species used in three of the soil erosion-control programs in China

Program	*Environmental situation*	*Species used*	*Region*
Plain Farmland Shelterbelts Program	Wind erosion	*Populus tremula*	Northeast China, East China, Yangtze River Basin, and Northwest China
	Strong Siberian wind	*Ulmus rubra*, *Larix gmelinii*, and *Picea asperata*	Bashang and Hebei
	Wind and sand fixation	*Salix matsudana* Koidz and *Artemisia desertorum*	Mu Us Sandland
Sloping Land Conversion Program	Wind erosion	*Robinia pseudoacacia*, *Platycladus orientalis*, *Pinus tabulaeformis*, *Pinus armandii*, *P. asperata*, *Populus davidiana*, and *Ulmus pumila*	Loess plateau
	Water and soil conservation	*R. pseudoacacia*, *Photinia serrulata*, *Phyllostachys pubescens*, *Pinus massoniana*, *Pinus elliottii*, *Dalbergia hupeana*, *Liquidambar formosana* Hance, *Corylus chinensis*, and *Phoebe bournei*	Hunan
Rocky Desertification Comprehensive Treatment Project	Soil conservation	*Pyrus pyrifolia* and *Hylocereus undatus*	Fuyuan, Xingren, and Guangxi

Plantation programs for the forestry industry, mainly composed of fast-growing and high-yield plantations, cover 18 provinces (Hebei, Inner Mongolia, Liaoning, Jilin, Heilongjiang, Jiangsu, Zhejiang, Anhui, Fujian, Jiangxi, Shandong, Henan, Hunan, Hubei, Guangdong, Guangxi, and Yunnan). The planned area of establishment was 4.7 million ha by 2005, 9.2 million ha by 2010, and 13.3 million ha by 2015; funded by a public–private partnership. Progress to date is uncertain.

In China, the general principles governing the choice of tree species include the following: matching species with site, giving priority to indigenous tree species, and unifying the economic benefit and ecological benefit. Based on different program objectives and different geographical locations, different tree species are being used. Examples of the range of species selected, together with the ways in which they are used in different programs, are given in Table 4.

The Tree North Shelterbelt Program has attracted international attention as the largest and most distinctive artificial ecological engineering project in China (Li *et al.*, 2012). Shelterbelt types used in the Tree North Shelterbelt Program include pure forest belts, roadside tree belts, mixed tree–shrub belts, mixed deciduous tree–shrub belts, mixed deciduous conifer tree belts, among others (Xu *et al.*, 1998). Efforts since 1977 have brought multiple benefits to local people by providing firewood and livestock fodder. The environment has benefitted especially in the form of farmland protection, soil and water conservation, wind reduction, and sand dune fixation (Li *et al.*, 2012). Li *et al.* (2012) warned that improvement of water use efficiency is important in these arid and semiarid regions, so careful choice of ecotype/clone within tree species is critical when establishing shelterbelts.

In the Plain Farmland Shelterbelts Program, *Populus tremula* is the main tree used. In Fujian province, *Phoebe bournei* cultivated as a monoclonal forest is a priority choice. It, however, requires better lands (lower slopes rather than upper slopes). Initial planting densities of 1500–1800 saplings per hm^2 are later thinned to final densities of 600–900 saplings.

To reduce the area of monoclonal forest in China, the planting of mixed species forest is recommended. Some examples are given below. In Fujian province, for cultivating the excellent timber tree *Manglietia yunnanensis*, 1800 saplings per hm^2 are planted at first, followed by later planting of mixes in the proportion 3–4:1. Mixes of *Cunninghamia lanceolata* and *M. yuyuanensis* are suitable in Fujian. In South China, *C. lanceolata* and *Pinus massoniana* are common mixed forest tree species. The former one mixed with *P. massoniana*,, *Cryptomeria fortunei*, *Cinnamomum camphora*, and *Schima superba* results in excellent timber yields. In North China, *Pinus koraiensis* mixed with *Fraxinus mandshurica* and *Lespedeza bicolor* Turcz,, and *Pinus tabuliformis* mixed with *Platycladus orientalis*, Oak, *Robinia pseudoacacia*, and *Amorpha fruitcosa* are recommended.

In stage II of the Greening Taihang Mountain Program in the middle of China, mixed forests are planted, in which *Acer truncatum* Bunge, Chinese honey locust, *Rhus typhina*, etc. are dominant tree species. The mixed forests account for 19.3% of the forest land in construction areas. In Beijing, Hebei, Shanxi, and Henan the proportion are 24.8%, 28.0%, 14.2%, and 10.1%, respectively.

Techniques and Species employed in the Establishment of Shelterbelt Trees in the programs

In Inner Mongolia, most of the shelterbelts are planted so as to form 400 × 400 m meshes (Figure 11), with each of the belts comprising three parallel lines of trees planted at 3 × 2 m intervals. This results in a porous structure that provides

maximum effective protection with reduced wind damage and debris buildup at the edges of the belt. The species used for the shelterbelts are fast-growing, medium-sized crown varieties that give good resistance in the prevailing soil and weather conditions. *Populus canadensis* Moench, *Populus euroamericana*, *Populus beijingensis*, and *Populus xianohei* are among the most widely used species, whereas a single row of *Amorpha fruticosa* is often planted on each side of the tree belt to provide understory protection.

Traditional planting approach for poplars was of 1-year-old rooted cuttings planted into pits within a 0.4 m trench. This technique was effective but costly. A newer technique planting unrooted 80–240 cm cuttings into a 70–220 cm slit or augured hole in the soil (depending on the depth to the water table) made by a mechanical device, either in spring (and buried over winter) or in autumn, provides good survival and subsequent growth. It is replacing the traditional technique. The conifer selection program has favored local provenances of *Pinus sylvestris* var. *mongolica* planted into raised beds *in situ* followed by taproot pruning. Selection programs continue to improve poplar and pine selection options particularly with improved survival and water use efficiency.

Effectiveness of Conservation Trees in Erosion Prevention

The implementation of the key forestry programs to some extent works to solve the water and soil erosion problem in China. The following section shows the effectiveness of Chinese key forestry programs in erosion prevention.

The area of water and soil erosion reduces year by year. After the implementation of the Natural Forest Protection Program, the area of erosion decreased 20% in Chongqing. In Hunan province, the erosion area reduced from 6000 km^2, before the implementation of the Yangtze River Basin Shelter Forest System Project, to 4700 km^2. Under the effectiveness of the Tree North Shelterbelt Program and Loess Plateau Comprehensive Control Program, approximately 230 000 km^2 of the erosion area is governed, which accounts for 50% of the total erosion area in Loess Plateau. By the end of 2010, Sanjiangyuan Ecological Protection and Construction Project in Qinghai Province brought approximately 750 000 km^2 erosion area under control.

The quantity of sediment flowing into the Yellow River and the Yangtze River reduces year by year. After the implementation of the Natural Forest Protection Program in 1998, the sediment concentration of the Yangtze River detected in Yichang in 2008 was 10% less than that in 1998 and the rate is reducing at approximately 1% per year. The sediment concentration of the Yellow River detected in Huyankou hydrometric station in Henan province reduced by 38% from 2000 to 2007. After the implementation of the Yangtze River Basin Shelter Forest System Project, the sediment concentration of Mianjiang, the trunk river of Ruijin in Jiangxi province, reduced from 0.32 kg m^{-3} 10 years ago to 0.27 kg m^{-3} now, in the rainy season.

The desertification of land has been under preliminary control. In eight provinces (Shanxi, Gansu, Ningxia, Inner Mongolia, Qinghai, Shaanxi, Hebei, and Heilongjiang), which are under the management of Tree North shelterbelt program, the area of desertification was reduced by 7300 km^2 from 2000 to 2007. The trend of desertification in three sand lands (Mu Us, Khorchin, and Hulun Buir) has been slowed, and initiatives are now focused on rebuilding and utilizing the desert. After the implementation of the Beijing–Tianjin Sand Storm Source Control Project, the density of PM10 (atmospheric particle matter with diameter of 10 μm or less) in Beijing reduced from 0.16 mg m^{-3} in 2000 to 0.11 mg m^{-3} in 2010. The number of the days when the ambient air quality attained Grade II (the national ambient air quality standard for urban residential, commerce–traffic mixed, common industrial, and rural areas in China) increased from 177 in 2000 to 285 in 2009.

The stony desertification of land has been under preliminary control. From 2005 to 2011, under the implementation of Rocky Desertification Comprehensive Treatment Project, there was approximately 19 800 km^2 rocky desertification land attaining effective governance. In Guizhou province, there were 14 400 km^2 karst area and 4800 km^2 rocky desertification area attaining effective governance from 2008 to 2012. A shift from arable farming to fruit farming has enabled farmers to stay on their land and farm economically while reducing soil erosion. As an example, in the Longhe Eco-Demonstration Area, through technical training for demonstration households, large areas of Pitaya (dragon fruit) plantations have been established. The Pitaya orchards, combining water-saving irrigation technology and interplanting grass technology, model a more sustainable way of farming that integrates new ways of land management with local culture. The introduction of 'ecological orchards' of fruit trees, such as Pitaya, has changed the land use from arable farming to agroforestry, has brought more economic stability to farmers, and improved the local ecological environment.

Other Benefits of Conservation Trees in the Landscape

Natural forest provides effective erosion protection and the forest resource base has increased gradually. Under the implementation of the Natural Forest Protection program, the timber production has reduced approximately 220 million m^3 and from this the reduction in forest resource consumption has reduced by approximately 380 million m^3. The stand volume has increased by approximately 725 million m^3. Given the percentage of cut-turn of 63%, this increased forest resource could convert into approximately US$58 billion, which is approximately 3 times the program investment.

The habitat of animals and plants has improved and the biological diversity is increasing. During the construction period of Sanjiangyuan Ecological Protection and Construction Project in Qinghai Province (2004–2010), there were population increases for the large mammals: Tibetan wild ass, Tibetan antelope, wild yak, and Bharal (blue sheep). For example, the total number of Tibetan antelope in Qinghai Province increased to 60 000 in 2010 from 30 000 in 1980.

As a consequence of the Ecological Protection and Construction Project, there have been changes in the industrial structure. According to data from state forest administration,

People's Republic of China, of 44 counties in the construction area of Natural forest protection program, the relationship between the primary, secondary, and tertiary industries changed from 86:3:11 in 2003 to 62:18:20 in 2009. The degree of dependency on timber production reduced from 90% at the beginning of the program to 52% at the end of 2010. Simultaneously, the forestry industry has diversified its activities and increased production value at a rate of 20% per year. The five provinces involved in the project had an increase in gross domestic product from US$16 billion in 1999 to US$97 billion in 2010.

Soil conservation programs have improved grain security. The implementation of Three North Shelterbelt Program effectively converted 'crop failure' to 'grain harvest.' In Northeastern China, Northern China, and the bend of the Yellow river approximately 225 000 km^2 of farmland is sheltered by forest. Under the implementation of the Plain Farmland Shelterbelts Program, 930 000 km^2 of the farmland in Henan province is protected by shelterbelts. In 2006 and 2007, production of grain in Henan province passed the billion kilogram mark. In Qihe country, Shangdong province, the grain output increased from 481 million kg in 2003 to 862 million kg in 2006.

Summary

Soil is one of the most precious resources. The loss of soil, particularly through the land degradation processes of wind and water erosion, is one of the most serious environmental problems the world is faced with, as it is reducing the means of producing food. Approximately 80% of the world's agricultural land was reported, almost 20 years ago, to suffer moderate to severe soil erosion and 10% to suffer slight to moderate erosion (Pimentel *et al.*, 1995). It is possible to alter the impact of these forms of erosion through the development and implementation of national policies and effective technologies, coupled with changes in land use and alternative economic opportunities for affected local communities. Without economic protection, soil degradation is most likely to continue in some other locality. Restorative technologies incorporating trees in the agricultural landscape have been developed in New Zealand and China and other countries to reduce soil loss. Where these technologies are being applied, they are proving to be effective in reducing erosion to low levels, thereby retaining both soil quantity and quality for the future.

Glossary

Coppicing Cutting trees close to the ground level to produce regrowth from the remaining stump.
Deep capture The extraction of nutrients by tree roots from soil depths beyond the reach of crop roots.
Pollarding Cutting back the crown of a tree but leaving the main trunk with the objective of harvesting wood and browse, producing regrowth beyond the reach of animals, or reducing the shade cast by the crown.
Protein (fodder) bank Stands of trees or shrubs established within a farm or pasture area to serve as a supplementary source of protein-rich fodder for livestock.
Silvopastoral Land use system in which trees are integral part of pasture land.

Introduction

Much of the world's agricultural land is degrading rapidly, and losing its productivity due to soil erosion and nutrient mining associated with continuous cropping without nutrient inputs and soil conservation. An estimated 24% of the world's land area has been degrading over the past 25 years, directly affecting the livelihoods of 1.5 billion people (Bai *et al.*, 2008). Approximately 19% of the degraded land is cropland (Bai *et al.*, 2008). According to the Global Assessment of Human-induced Soil Degradation, soil erosion affects 83% of the global degraded area (Bai *et al.*, 2008). Soil degradation by erosion alone affects 1966 million hectares worldwide (Lal, 2007). In Africa, the annual average nutrient (NPK) loss is estimated at 9–58 kg ha^{-1} $year^{-1}$ in 28 countries and 61–88 kg ha^{-1} $year^{-1}$ in the remaining 21 (Chianu *et al.*, 2012). Recent global analyses show that N limitation is particularly widespread in all ecosystems (LeBauer and Treseder, 2008; Liu *et al.*, 2010). The global average N recovery rate is 59%, indicating that nearly 41% of N inputs are lost in ecosystems (Liu *et al.*, 2010). Almost 80% of African countries experience N deficit or N stress problems, which, along with poverty, cause food insecurity and malnutrition (Liu *et al.*, 2010). In total, 29% of the global cropland area experiences P deficits (MacDonald *et al.*, 2011).

Conventionally in modern agriculture, increased productivity has been achieved mainly through application of synthetic inorganic fertilizers. However, the increasing price of synthetic fertilizers and the inability of poor farmers to gain access to them pose severe constraints on their widespread use. Although organic matter may be an alternative source of nutrients, neither animal manure nor green biomass is usually found in adequate quantities to meet the high application rates (10–40 Mg ha^{-1} $year^{-1}$) required to meet the nutrient requirements of crops (Mafongoya *et al.*, 2006). Some authors have therefore argued that improving fertilizer use efficiency by a combination of organic and inorganic nutrients is vital to the long-term sustainability of global agriculture. Within this important goal there is great potential for the more effective utilization of biological N-fixation (BNF), which is virtually without cost. BNF accounts for 60% of N production (Zahran, 1999) and 16% of the current global N input (Liu *et al.*, 2010). However, in Africa and South America, BNF is the single largest N source, accounting for 32–34% of the N input (Liu *et al.*, 2010). In this respect its further use would, at the least, ease the pressure for land through the rehabilitation of degraded areas (Herridge *et al.*, 2008). However, BNF can also play a greater role in sustainable agriculture as it increases N recovery rates in addition to reducing the need for synthetic fertilizers. In this article, the authors present a review of options for more efficiently harnessing BNF for improved food security within the important debate about the future of global agriculture. They specifically explore the potential role that N-fixing trees can play in land rehabilitation for food crops and pastures and the improved productivity of saline and impoverished soils. In this context it is interesting that with the advent of high-yielding crop varieties requiring full sunlight, the tendency has been to remove trees including N-fixers from many food and cash cropping systems.

Fertilizer Trees: Definition

The term 'fertilizer trees' is commonly used to refer to the utilization of N-fixing leguminous trees in cereal production systems to improve the availability of N to crops (Ajayi *et al.*, 2011; Akinnifesi *et al.*, 2010; Mafongoya *et al.*, 2006), but this usage has generally excluded the use of such trees in pastures

Table 1 Cereal yield response to fertilizer trees summarized from studies across sub-Saharan Africa

Cereal crop	*Species*	*Number of studies (N)*	*Mean yield (Mg ha^{-1} ± SE)*	*Yield increase (Mg ha^{-1} ± SE)*	*Increase[f] (% ± SE)*
Maize	Pigeon pea[a,b]	24 (69)	2.1 ± 0.2	0.7 ± 0.1	89.8 ± 13.2
	Tephrosia[a,b]	28 (177)	2.1 ± 0.1	0.9 ± 0.1	206.3 ± 42.6
	Leucaena[b,c]	6 (78)	2.5 ± 0.2	1.0 ± 0.1	94.5 ± 12.2
	Sesbania[a,b]	42 (262)	3.0 ± 0.1	1.7 ± 0.1	318.1 ± 82.5
	Gliricidia[d]	15 (127)	3.2 ± 0.1	2.2 ± 0.1	295.9 ± 27.8
	Faidherbia[e]	12 (88)	4.5 ± 0.2	2.5 ± 0.2	184.6 ± 33.9
	Synthetic fertilizer	72 (384)	3.8 ± 0.1	2.2 ± 0.1	383.8 ± 40.5
Sorghum	Gliricidia[d]	4 (10)	1.5 ± 0.1	−0.1 ± 0.1	93.8 ± 5.3
	Faidherbia[e]	5 (14)	1.0 ± 0.2	0.3 ± 0.1	144.4 ± 22.8
	Sesbania[a,b]	2 (24)	1.8 ± 0.1	0.6 ± 0.1	180.44 ± 19.1
Millet	Vachellia[e]	3 (11)	0.7 ± 0.1	−0.04 ± 0.1	107.8 ± 14.4
	Faidherbia[e]	5 (13)	1.2 ± 0.1	0.4 ± 0.1	149.3 ± 14.4

[a]Relay cropping.
[b]Improved fallow.
[c]Alley cropping.
[d]Intercropping.
[e]Parkland.
[f]Increase over the no-input control.
Abbreviation: N = number of data points representing either sites or years within a study.
Note: The yield increase is the difference between the treatment and the control (no input) on the same site. The percent increase is increase in yield over the control in percentage terms, and this was calculated as 100*(yield increase)/control yield.

and for the rehabilitation of degraded land. The so-called 'N-fixing tree' is a tripartite symbiotic system involving an association between the plant, N-fixing bacteria, and mycorrhizae-forming fungi (Nygren *et al.*, 2012). Atmospheric N-fixation by symbiotic, single-celled bacteria (*Rhizobium*) in root nodules is common in 340 species of the family Leguminosae. N-fixation also occurs in over 200 nonleguminous plants species in 25 genera of 8 families associated with *Frankia* (Actinomycetes), which are filamentous bacteria (Franche *et al.*, 2009; Russo, 2005). The broader definition of 'fertilizer' trees used here includes the legume–*Rhizobium* as well as nonlegume–*Frankia* symbioses.

There are a large number of agroforestry practices that capitalize on BNF from fertilizer trees for the supply of N and organic matter to annual and perennial crops. These include alley cropping, improved fallows, cereal-tree legume intercropping, relay cropping, biomass transfer, fodder banks, multistrata agroforestry, parklands, and silvopastoral systems. Among the widely used fertilizer trees are acacia (*Acacia* spp.), acaciella (*Acaciella* spp.), albizia (*Albizia* spp.), alder (*Alnus* spp.), calliandra (*Calliandra calothyrsus*), casuarina (*Casuarina equisetifolia*), erythrina (*Erythrina* spp.), faidherbia (*Faidherbia albida*), flemingia (*Flemingia* spp.), gliricidia (*Gliricidia sepium*), inga (*Inga edulis*), leucaena (*Leucaena* spp.), sesbania (*Sesbania* spp.), parkia (*Parkia biglobosa*), tagasaste (*Chamaecytisus palmensis*), tephrosia (*Tephrosia* spp.), tamarind (*Tamarindus indica*), and vachellia (*Vachellia* spp.). Hereafter reference will be limited to these common names.

Benefits of Fertilizer Trees

Increased Crop Productivity

Several studies have reported the beneficial effects of fertilizer trees on yields of food crops. According to a meta-analysis of 94 peer-reviewed publications across sub-Saharan Africa (Sileshi *et al.*, 2008a), maize yields increased by 0.7–2.5 Mg ha^{-1} over the no-input control, which translates to an 89–318% increase (**Table 1**). Under similar conditions, the recommended rate of synthetic fertilizer led to 384% increases over the control (**Table 1**). Robust estimates indicate that the 95% confidence intervals of maize yield increased by faidherbia (2.0–2.7 Mg ha^{-1}), gliricidia (1.8–2.4 Mg ha^{-1}), and synthetic fertilizer (1.9–2.3 Mg ha^{-1}) overlap completely. Recent analyses (Sileshi *et al.*, 2011, 2012) also showed that maize yields are more stable in maize intercropped with leucaena and gliricidia than in fully fertilized sole maize at sites in Malawi, Zambia, and Nigeria. In terms of increased crop yields, synergistic effects of synthetic fertilizer and fertilizer trees were noted. Yield increases from fertilizer trees were substantial even when associated with 25–50% of the recommended dosages of synthetic fertilizer (Sileshi *et al.*, 2011, 2012).

Although fewer data are available for millet and sorghum (mostly short term in nature), increases in yields relative to the control have been substantial with fertilizer trees (**Table 1**). An important gain that is usually under-reported is the stover yield. Stover is a critical fodder in cereal-livestock mixed farming systems in Africa. Using empirical distributions of stover to grain fresh weight ratios of 0.8:1.0 the authors estimate that an additional 0.2–2.0 Mg ha^{-1} year^{-1} of stover can be produced by the use of fertilizer trees (**Table 1**), an important contribution to livestock feed when grass is in short supply. These yield increases are also associated with large variability attributable to tree species, site conditions (soils, rainfall, elevation), and management factors (Bayala *et al.*, 2012; Sileshi *et al.*, 2008a, 2010). Although in the short term crop yields may be reduced due to tree competition, in the long term favorable soil conditions are expected to improve crop productivity.

Through biomass transfer, fertilizer trees can also be used to increase vegetable productivity. Biomass transfer is

[b]Increase over the no-input control.
[c]Average of 31 farmers' fields.
[d]Average of 12 farmers' fields.
Note: The yield increase is the difference between the treatment and the control (no input) on the same site. The percent increase is increase in yield over the control in percentage terms, and this was calculated as 100*(yield increase)/control yield.

essentially moving tree biomass (prunings) produced in one part of the farm (e.g., in protein banks, fallows, etc.) to another (e.g., a vegetable garden). Usually 4–12 Mg ha^{-1} of the leafy biomass (on dry matter basis) is applied to crops, and this has been shown to increase yields of cabbage, rape, onion, tomato, and garlic in trials on research stations as well as farmers' fields in Africa (Table 2).

Increases in productivity have been demonstrated in cash crops associated with fertilizer trees. For example, shade trees reduce the stress on crops such as coffee and cacao by ameliorating adverse climatic conditions and nutritional imbalances, thus increasing overall system productivity in multistrata agroforestry (Beer *et al.*, 1998). In Western Ghana, Isaac *et al.* (2007) found higher above ground cocoa biomass (39.6 Mg ha^{-1}) under albizia canopies compared to 22.8 Mg ha^{-1} for sole cocoa. Above-ground dry matter of cocoa also declined along a spatial gradient away from albizia trees (Isaac *et al.*, 2007). In India, the agronomic yield of large cardamom doubled under 5–15-year-old alder stands and peaked between 15 and 20 years of age (Russo, 2005).

Soil Rehabilitation Services

To understand how the above yield benefits are achieved one needs to examine how adding fertilizer trees into the agricultural landscape restores soil fertility and promotes the biological processes and ecological functions that together rehabilitate degraded land. These are the critical processes that benefit the farmer in particular and society in general. Among these important services are nutrient cycling, increased availability of macronutrients (extractable N, P, and K), cations and improvement in soil pH, increased organic matter (SOM), enhanced biological activity, improved soil physical properties, and better water relations.

Improvement in soil nutrient cycling

Fertilizer trees have potential to provide N in quantities sufficient to support moderate crop yields through (1) N inputs from biological N_2 fixation and retrieval of nitrate from deep soil layers and (2) cycling of N from plant residues and manures (Buresh and Tian, 1998). However, fertilizer trees cannot produce new resources of other nutrients, although they can increase their availability and uptake by crop plants through different mechanisms. The cycling of P from organic materials is also normally insufficient to meet the P requirements of crops (Buresh and Tian, 1998). As they access deep water reserves beyond reach of annual crops, tree roots act as a safety net to capture nutrients leached from the topsoil and return these to the soil surface as litter. The presence of trees improves nutrient use efficiency by providing a safety net to recover nutrients leached from the topsoil during intense rainfall and return them to the surface horizons on which crop roots primarily depend, in a manner analogous to the hydraulic lift of water.

N availability and uptake

The percentage of N derived from the atmosphere (NDFA) is more than 59% according to a recent analysis of 38 cases using N isotopic analyses (Nygren *et al.*, 2012). Under humid and sub-humid conditions, on average NDFA was 69% in

young trees and 63% in periodically pruned trees compared to 54% in free-growing (nonpruned) trees (Nygren *et al.*, 2012). The average N-fixation for 16 variable fertilizer tree species was found to be 246 kg N ha^{-1} $year^{-1}$, but much higher (300–650 kg N ha^{-1} $year^{-1}$) in improved fallows and protein banks where trees are managed by pruning or coppicing (Nygren *et al.*, 2012). These values are much higher than the global estimates (23–176 kg N ha^{-1} $year^{-1}$) for food legumes and herbaceous pasture and fodder legumes (Herridge *et al.*, 2008). Among the nonlegume–*Frankia* associations, N-fixation has been estimated at 40–320 kg N ha^{-1} $year^{-1}$ for alder (Russo, 2005) and casuarina 73 kg N ha^{-1} $year^{-1}$ (Nygren *et al.*, 2012). Although the annual N inputs vary widely between species and even among provenances of the same species across different locations and stand age, the amounts reported are enough to fulfill crop N needs for sustained yield (Nygren *et al.*, 2012).

In Latin American coffee and cacao agroforestry, pruning residues and litter fall from shade trees have been shown to contribute 60–340 kg N ha^{-1} $year^{-1}$ (Beer *et al.*, 1998). In coffee plantations in Costa Rica, erythrina contributed over 300 kg N ha^{-1} $year^{-1}$ (Kass *et al.*, 1997). Various studies across the globe have documented significant increases in N stocks under fertilizer trees compared to crop monocultures (**Table 3**). According to a study on cacao agroforestry in Ghana the ammonium sulphate fertilizer equivalence of albizia leaves is 21–72 kg N ha^{-1}; thus, the leaves could substitute 29–63% of fertilizer when applied to soil at 2.5 Mg ha^{-1} (Anim-Kwapong, 2006). In a silvopastoral system with king grass in Costa Rica, erythrina contributed 266 kg N ha^{-1} $year^{-1}$ (Kass *et al.*, 1997). Direct below-ground transfer of N fixed by legume trees to associated non-N-fixing crops and forage grass has been widely documented (Nygren *et al.*, 2012; Sierra and Nygren, 2006). This can take place via root exudates or common mycorrhizal networks (Nygren *et al.*, 2012). In coffee agroforestry approximately 30% of the N effectively fixed by leucaena, calliandra, and erythrina was transferred to the associated coffee trees (Snoeck *et al.*, 2000). In Sri Lanka, up to 21% of N in grass was derived from transfer of N fixed by gliricidia and leucaena (Jayasundara *et al.*, 1997).

A review of studies in parklands across Africa shows that N availability is higher under faidherbia than in the open field (**Table 3**). N availability can also be increased significantly under improved fallows and alley cropping of fertilizer trees compared to control plots without trees (**Table 3**). In gliricidia-maize-pigeon pea intercropping in southern Malawi 191–302 kg N ha^{-1} could be realized from gliricidia prunings (Akinnifesi *et al.*, 2010).

Although N inputs from fertilizer trees may be high, the N recovery by crops is usually 10–30% of the N applied as prunings per season, depending on the quality of residues. Much of the N from organic inputs (50–80%) is not used by the crop. Low N recovery is partly caused by a lack of synchrony between the N release and demand by the associated crop. Nevertheless, N use efficiency by cereals is higher from fertilizer trees than from synthetic fertilizer. For example, in alley cropping in Nigeria, N use efficiency of synthetic fertilizer was 10–22% compared to 49% in gliricidia and 59% in albizia

Table 3 Increase (%) in N and P stocks due to fertilizer and nutrient uptake by crop relative to crop monoculture or areas outside tree influence

(Okogun *et al.*, 2000). N uptake by crops is usually improved when cereals are associated with fertilizer trees (**Table 3**). Soil amendment with small dosages of inorganic fertilizer (25–50% of recommended rate) further increases N uptake. For example, N uptake increased by over 245% when the maize crop in the alleys between these trees was amended with 40–80 kg N ha^{-1} of synthetic fertilizers in Nigeria (Okogun *et al.*, 2000). Similarly, N uptake significantly increased when gliricidia plots were amended with synthetic N and P fertilizers (Mweta *et al.*, 2007).

The question arising from all of the above is: To what extent can fertilizer trees substitute for inorganic N fertilizers? The answer it seems depends on the desired crop yield. Typically, smallholder farmers in SSA have maize yields of 1–2 Mg ha^{-1}. 1 Mg ha^{-1} maize crop requires 20 kg N ha^{-1}. Tree pruning applied at 5 Mg ha^{-1} provides N input of 60–150 kg ha^{-1} (Palm, 1997), and this can support maize yields of up to 4 Mg ha^{-1} without any added synthetic fertilizer. In gliricidia-maize intercropping in Malawi, it is possible to reduce synthetic fertilizer use by 48 kg N ha^{-1} $year^{-1}$ (Dong-Gill, 2012) while still maintaining yields of up to 4 Mg ha^{-1} (Akinnifesi *et al.*, 2010). For higher yields, although BNF may supply adequate N, supplementation with inorganic fertilizers may be required to provide sufficient P and K.

P availability and uptake

Fertilizer trees can contribute to P availability, either directly by releasing tissue P during decomposition and mineralization or indirectly by acting on chemical processes that regulate P adsorption–desorption reactions. Compared to annual crops, tree root systems are more extensive. This increases the exploration of larger soil volumes, resulting in enhanced uptake of P and other nutrients. Trees may also access soil P from relatively recalcitrant pools not utilized by crops (Buresh and Tian, 1998). The symbiotic association between fertilizer trees and mycorrhizal fungi can also improve the capacity of the plant to take up P. A number of empirical studies have documented higher soil P concentrations and uptake by crops in the presence of fertilizer trees (**Table 3**). However, it is important to note that fertilizer tree innovations will not eliminate the need for P inputs in P deficient soils. Plant materials, even when added in large amounts, may provide less P than that required to obtain adequate crop yields. This inadequacy is due to a low concentration of P (<3 g kg^{-1}) in plant residues. For example, >18 kg P ha^{-1} is required to produce maize yield of 2 Mg ha^{-1}. However, application of even high-quality residues at 5 ton ha^{-1} adds only 15 kg P ha^{-1} crop (Palm *et al.*, 1997). Therefore, soil amendment with soluble mineral P fertilizers or phosphate rocks is required to obtain adequate crop yields in P-limited soils (Buresh and Tian, 1998). The added P can be recycled through fertilizer trees in their leaf litter and root turnover.

Cation concentrations and improvement in soil pH

Increases in cations and soil pH and decrease in aluminium saturation and improvement in the conditions for plant growth in acid soils have been associated with application of tree prunings (Mafongoya *et al.*, 2006). Increases in soil cation concentrations usually results from recycling through the biomass fertilizer trees. Several studies in parklands in the Sahel indicate that exchangeable K in the 0–10 cm soil is 43–133% higher under faidherbia than in the open (Boffa, 1999). Similarly, Ca was 2–270% higher, while Mg was 0–78% higher under faidherbia than in the open. In Ethiopia, Kamara and Haque (1992) found that K concentrations were higher by 150–178% beneath faidherbia than in the open. Fertilizer trees could minimize nitrate leaching and soil acidification both by decreasing drainage and recycling leached nutrients. Thus, in acid soils fertilizer tree prunings could be used as a 'liming' material, thus providing resource-poor farmers with an inexpensive biological means for alleviating soil acidity.

Increased soil organic matter

Fertilizer trees enhance soil organic matter (SOM) both through production of SOM and reducing losses due to erosion. A compilation of studies in parklands of West Africa (Boffa, 1999) indicates 11–100% higher SOM under faidherbia trees than in open areas. In Ethiopia, SOM under faidherbia was 69–107% higher than in the open (Kamara and Haque, 1992). Increased soil organic carbon (SOC) content, particularly in the light fraction, is known to improve aggregate stability, porosity, hydraulic conductivity, and soil structures that resist erosion.

Improvement in soil biological properties

The impact of fertilizer trees on soil biological properties may be assessed by changes in abundance, diversity, and community structure of soil fauna and flora, microbial biomass, enzyme activity (e.g., respiration), and soil pests and weeds. Soil fauna play a key part in litter decomposition through their interactions with plants and soil microbial communities. During decomposition, the organic forms of nutrients in the litter are converted to inorganic forms that can be absorbed by the growing plants. In addition, the activities of soil fauna improve soil water infiltration and storage, which is becoming increasingly important in agricultural sustainability in arid climates (Sileshi and Mafongoya, 2006; Tian *et al.*, 2001).

Even in highly degraded soils, fertilizer tree species have been shown to restore soil fauna in a relatively short time (Sileshi and Mafongoya, 2006; Sileshi *et al.*, 2008b; Tian *et al.*, 2001). At two sites in eastern Zambia, earthworm densities were found to be significantly higher in maize intercropped with vachellia, calliandra, gliricidia, and leucaena compared with fully fertilized sole maize (Sileshi and Mafongoya, 2006). In another study in eastern Zambia, earthworm abundance was 2–3 times higher in maize planted after sesbania +tephrosia and pure pigeon pea fallows compared with sole maize (Sileshi *et al.*, 2008b).

N-fixing trees have been shown to modify populations of microflora, microbial biomass, and enzyme activity (Mafongoya *et al.*, 1997; Tian *et al.*, 2001; Wick *et al.*, 1998). For example, at Domboshawa in Zimbabwe, fungal and actinomycetes populations differed with the quality and quantity of fertilizer tree biomass as well as the method of application. Actinomycetes populations were six to nine times higher where vachellia and calliandra biomass was surface-applied than when incorporated in the soil (Mafongoya *et al.*, 1997).

The microbial biomass is also part of the active SOM pool, and has been proposed as an indicator of state and change of total SOM. Enzyme activity in the soil is an indicator of soil

biological status. For example, phosphatases are important in the P cycle because they provide P for plant uptake by releasing PO_4, and acid phosphatase can provide a potential index for a soil to mineralize organic P. β-glucosidase catalyzes the conversion of cellulose to glucose, and as such important energy sources for micro organisms. In long-term experiments carried out at three sites in southern Nigeria (Wick *et al.*, 1998), β-glucosidase increased by 41–119% with leucaena relative to continuous cropping of maize/cassava (Wick *et al.*, 1998). Alkaline phosphatase increased by 24–149% with leucaena relative to the control (Wick *et al.*, 1998).

Fertilizer trees in certain agroforestry practices can also reduce soil insect pests and weeds (Sileshi *et al.*, 2008c). For example, termite damage to maize was reduced by improved fallows involving fertilizer trees in Zambia (Sileshi *et al.*, 2005). One of the most important aspects is the control of problematic weeds such as spear grass (*Imperata cylindrical*). In Nigeria, hedgerows of leucaena and gliricidia reduced the population of spear grass by 51−67%, above-ground biomass by 78−81%, and below-ground rhizomes by 90−96% compared to a bush fallow (Anoka *et al.*, 1991). In a study at Pucallpa in the Peruvian Amazon, weed biomass was 40–63% less in inga fallows compared to natural fallows (Lojka *et al.*, 2012). In alley cropping, albizia and gliricidia have been shown to reduce weed in Nigeria (Okogun *et al.*, 2000).

Fertilizer tree fallows have also been shown to reduce the parasitic witch weeds (*Striga* spp.) problem, which is usually associated with low soil fertility in Africa (Gacheru and Rao, 2001; Sileshi *et al.*, 2008c). Sesbania was better than many other species in reducing *Striga asiatica* infestation in maize in eastern Zambia (Sileshi *et al.*, 2008c). The reduction in infestation was significantly influenced by the quantity of biomass from fertilizer trees (Sileshi *et al.*, 2008c). In East Africa, reduction of *Striga hermontica* infestation by legume fallows depended on the rate of decomposition and nitrogen mineralization of organic residues (Gacheru and Rao, 2001). Reduction in weed problems is due to shading and smothering of the weeds by trees and the thick mulch layer formed by the leaf litter from the trees subsequently depleting the weed seed-bank. Many legume species release a wide range of allelochemical compounds, which can inhibit weed seed germination or reduce weed vigor (Sileshi *et al.*, 2008c).

Improvement in soil physical properties

Among the commonly used indicators of soil physical properties are soil depth, bulk density, aggregate stability, infiltration rates, water-holding capacity, and penetration resistance. Soil bulk density is a direct measure of soil compaction. Soils with low bulk density, although open-textured and porous, are susceptible to erosion, poor water retention, and oxidation of SOM and loss of SOC. In contrast, soils with high bulk density have lower porosity. Various studies indicate improvement in bulk density, aggregate stability, and porosity due to fertilizer trees. In sandy loam soil in the pre-Amazon region of Brazil, bulk density, total porosity, and soil aeration were substantially improved in alley cropping with leucaena, pigeon pea, acacia, and their mixtures over a period of three years (Aguiar *et al.*, 2010). In gliricidia, leucaena, Vachellia, and sesbania rotational fallows in Zimbabwe and Zambia soil bulk density was up to 12% lower and aggregate stability was higher by 18–36% compared to sole maize crops (**Table 4**). Pore density was also significantly higher in vachellia and sesbania fallows (285–443 m^{-2}) compared to continuous maize (256 m^{-2}). The pore density was significantly higher in Vachellia and sesbania fallows (4521–8911 m^{-2}) compared to continuous maize (2689–3938 m^{-2}). The mean pore sizes were lower in continuous maize and higher in the fertilizer tree fallows (Nyamadzawo *et al.*, 2008a). The mean pore sizes at 5 cm tension were 0.07–0.12 mm in fallows relative to continuous maize, which were 0.03 mm.

The improvement in soil structure was also associated with increased drainage, especially during wet periods. In eastern Zambia and Zimbabwe, steady-state infiltration rates were 42–600% higher when maize was rotated with gliricidia, leucaena, vachellia, sesbania, and tephrosia compared to continuously grown sole maize (**Table 4**). Time to water runoff was also longer by 40–133% and drainage was improved by 88–900% compared to continuous sole maize. The soil in maize planted following improved fallows had lower penetration resistance compared with monoculture maize at various sites in eastern Zambia (**Table 4**).

Reduced penetrometer resistance and increased water infiltration imply reduced water runoff and soil erosion. The improvement under fertilizer trees was evident from the longer time to runoff measured in maize fertilizer tree rotations compared to sole maize in Zambia and Zimbabwe (**Table 4**). Land under fertilizer trees has been shown to be less susceptible to runoff and erosion than continuous maize. According to Fagerström *et al.* (2002), in an upland rice cropping system in northern Vietnam, tephrosia fallows and hedgerows effectively prevented nutrient losses by erosion. Runoff and soil losses were also lower in maize grown with fertilizer trees compared to continuous maize in Zimbabwe (**Table 4**). Soil loss was 30–100% higher under continuous maize than under fertilizer tree fallows (Nyamadzawo *et al.*, 2006; Nyamadzawo *et al.*, 2012).

As they increase hydraulic conductivity and reduce runoff losses, fertilizer trees improve water retention, storage, and availability to associated crops. At Domboshawa in Zimbabwe 75–80% of the total available water was retained at suction <33 kPa in the top 0–15 cm depth under vachellia fallows (Nyamadzawo *et al.*, 2012). Soil water stored in 2-year sesbania-improved fallows was greater than in continuously cropped fertilized or unfertilized maize in eastern Zambia (Phiri *et al.*, 2003). In parklands in Ethiopia, the amount of available water under faidherbia was twice that outside the tree canopy (Kamara and Haque, 1992). Similarly, in Malawi, soil moisture in the 0–15 cm soil was 4–53% higher under faidherbia than outside the tree canopy (Rhoades, 1995). The trees canopy also intercepts water and channels it down to the soil, thus contributing soil water recharge through macropores created by roots and increased microbial activities. Phiri (2002) recorded greater rainfall interception by sesbania tree canopies indicated by increased moisture storage and sub-soil moisture recharge.

The role of fertilizer trees in improving water use efficiency (WUE) has recently been demonstrated with long-term field studies in Africa (Sileshi *et al.*, 2011). In rain-fed agriculture, rain use efficiency (RUE) defined as the ratio of above-ground net primary production to annual rainfall provides

Table 4 Changes in soil physical properties (0–20 cm) due to fertilizer trees (FT) in improved fallow and the control (sole maize) and the % change (%Δ) at Msekera, Kagoro, and Kalunga sites in Zambia and Domboshawa in Zimbabwe

information similar to WUE. Sileshi *et al.* (2011) analyzed variations in RUE with leucaena in three long-term experiments conducted in Zambia and Nigeria. At the two sites in Zambia, maize intercropped with leucaena achieved 191–197% higher RUE compared to sole maize continuously cropped without nutrient inputs. At the Nigerian site, RUE was 139–202% higher in maize planted between leucaena hedgerows compared to the control (Sileshi *et al.*, 2011). According to another study at Makoka (Chirwa *et al.*, 2007), WUE was higher in maize intercropped with gliricidia than in the sole maize and maize+pigeon pea intercropping. At another site in eastern Zambia, WUE was 202% higher in sesbania fallows compared to continuous sole maize (Phiri, 2002).

Carbon Sequestration and Greenhouse Gas Mitigation Potential

A growing number of studies have also demonstrated that fertilizer trees can sequester significant amounts of C both in the soil and in their woody biomass and mitigate greenhouse gas (GHG) emissions. In Mali, Takimoto *et al.* (2008) estimated 70.8 Mg C ha^{-1} in the top 40 cm of the soil in parklands dominated by faidherbia. SOC increases of 3–70% under faidherbia canopy have also been reported in the Sudan (Rhoades, 1995). At several sites in Malawi, SOC was 3–30% higher under faidherbia canopy than in the open (Rhoades, 1995). According to Sierra and Nygren (2006), gliricidia trees

in pastures contributed 16–18 Mg C ha^{-1} to soil over 12 years. In a 19-year-old gliricidia alley cropping in Costa Rica, the SOC pool was 16–23% higher than the sole crop (Oelbermann *et al.*, 2004). In the 19th year of alley cropping, SOC was significantly higher in the alley crop (3.2%) compared to the sole crop (2.4%) (Oelbermann *et al.*, 2004). Similarly, in a 19-year-old alley cropping with erythrina in Costa Rica, C inputs from tree prunings were 4.01 Mg C ha^{-1} $year^{-1}$ (Oelbermann *et al.*, 2006). The input from crop residues was significantly greater in the erythrina alley crop for maize (1.34 Mg ha^{-1} $year^{-1}$) and beans (0.35 Mg ha^{-1} $year^{-1}$) compared to the sole crop (Oelbermann *et al.*, 2006). Nygren (1995) showed that C input from prunings of erythrina in Costa Rica ranged from 2.3 to 5.2 Mg ha^{-1} $year^{-1}$ at a tree density of 625 trees ha^{-1}. In alley cropping with leucaena in Nigeria, SOC increased by 108% in the 0–15 cm soil as compared to the control without a hedgerow (Kang *et al.*, 1999). In Zimbabwe, SOC was 1.7 times higher in Vachellia fallows than continuous sole maize (Nyamadzawo *et al.*, 2008b). SOC stocks within 0–30 cm depth under 5-year-old rotational woodlots (15.8–25.6 Mg ha^{-1}) were higher than in soils that had been continuously cropped for the same time period (13 Mg ha^{-1}) in Tanzania (Kimaro *et al.*, 2011). According to Kaonga and Coleman (2008) SOC stocks under tephrosia, sesbania, and pigeon pea were higher (27.3–31.2 Mg ha^{-1}) than under fully fertilized sole maize (26.2 Mg ha^{-1}) and unfertilized sole maize (22.2 Mg ha^{-1}) in eastern Zambia. The above-ground plant C input was estimated at 2.8 Mg C ha^{-1} $year^{-1}$ for tephrosia, 2.7 Mg ha^{-1} $year^{-1}$ for sesbania, and 2.5 Mg ha^{-1} $year^{-1}$ for pigeon pea, which was comparable to 2.7 Mg ha^{-1} $year^{-1}$ recorded for fully fertilized sole maize (Kaonga and Coleman, 2008). In Malawi, Makumba *et al.* (2007) found that soil C in a gliricidia–maize intercropping roughly doubled after 7 and 10 years compared to sole maize. A more recent reanalysis of the data from Makumba *et al.* (2007) found an annual net gain of 3.5 Mg C ha^{-1} $year^{-1}$ in the soil (Dong-Gill, 2012). With the potential for N_2O mitigation of 0.12–1.97 kg N_2O–N ha^{-1} $year^{-1}$) the gliricidia–maize intercropping was estimated to mitigate 3.5–4.1 Mg CO_2 eq. ha^{-1} $year^{-1}$ (Dong-Gill, 2012).

Estimates of above-ground C storage are also substantial. In cacao agroforestry in Indonesia, C stock in biomass was estimated at 31.4 Mg C ha^{-1} in 15-year-old gliricidia (Simley and Kroschel, 2008). Similarly, in Costa Rican cacao agroforestry, erythrina stored 40 Mg C ha^{-1} (Oelbermann *et al.*, 2006). In 5-year rotational woodlots in Tanzania, carbon sequestered in wood of fertilizer trees ranged from 11.6 to 25.5 Mg ha^{-1} (Kimaro *et al.*, 2011). Wood C accumulation rates ranged from 2.3 to 5.1 Mg C ha^{-1} $year^{-1}$ in acacia species (Kimaro *et al.*, 2011). A 6-year stand of faidherbia in Tanzania accumulated 9.4 Mg ha^{-1} of wood C at a 5 m by 5 m spacing (Okorio and Maghembe, 1994). In parkland in Mali, faidherbia accumulated 20.3 Mg ha^{-1} (Takimoto *et al.*, 2008). This can play a critical role in mitigation of climate changes as they favor nutrient recycling and C sequestration in crop and pasture land. However, the potential for accumulation of ecosystem C by fertilizer trees depends on site characteristics and planting densities. Therefore, accurate methods are required to determine change in C with the inclusion of fertilizer tree innovations in the various farming systems.

Provision of Products

Most N-fixing trees provide various products including wood, fruits, edible seeds, and fodder that are rich in protein and increase pasture productivity.

Wood and Wood Products

Several studies have indicated production of substantial amounts of firewood and timber from fertilizer trees planted on farmland (**Table 5**). In acid soils in Peru, inga produced up to 8–12 Mg ha^{-1} $year^{-1}$ of wood (Lojka *et al.*, 2012). Russo (2005) reported wood production of 15–20 m^3 ha^{-1} $year^{-1}$ in alder. A stand of 30-year-old trees with a density of 35 trees ha^{-1} yielded 70 m^3 ha^{-1} of timber, 18.3 Mg ha^{-1} of dry fuelwood (Russo, 2005). Several studies have also indicated production of substantial amounts of firewood in Africa (**Table 5**). Assuming per capita dried firewood consumption of 486 kg (0.67 m^3) $year^{-1}$ (Ndayambaje and Mohren, 2011), wood yields of the various species would be sufficient to meet the household fuelwood demands for 1–17 families of 6 people (**Table 5**). Such high wood yields exemplify the potential of fertilizer trees in meeting local firewood demands, especially in Africa where the population depends on extraction of wood from forests due to lack of alternatives in energy supply. As forest resources continue to degrade, access to firewood declines, and rural women have to walk increasingly longer distances in search of firewood. Planting of fertilizer trees on farmland can increase access to firewood by women, and thus the time and labor spent in search of firewood can be reallocated to food production and childcare.

Fruits and Edible Seeds

Some fertilizer trees (e.g., tamarind, parkia, pigeon pea, *Tetrapleura tetraptera*, etc.) produced edible seeds or kernels. For example, pigeon pea seeds are a rich source of protein, carbohydrates, minerals, and vitamins, making it an ideal supplement to the traditional starch-based diets of Africa and Asia, which are generally protein-deficient (Odeny, 2007). The edible pulp of tamarind is consumed fresh or used to make syrup, juice concentrates, and exotic food specialities such as chutney, curries, pickles, and meat sauces. In the Sahel, parkia seeds are a valuable source of condiment locally called 'soumbala,' which is an important source of protein (Kalinganire *et al.*, 2008).

Fodder and Pasture

Scarcity of forage and lack of access to high-quality feed are major constraints to livestock productivity, especially in the semiarid areas. Silvopastoral management including protein (fodder) banks and grazing systems involving fertilizer trees may partly overcome these problems. Protein banks allow animals to be stall-fed with fodder from trees such as gliricidia, calliandra, or various species of leucaena, pterocarpus, and others grown in blocks on farmland. Alternatively, grazing systems allow livestock to graze on pasture under widely

spaced trees (e.g., alley farming) or scattered trees (e.g., parklands).

In the more extensive grazing areas of South America, Asia, Australia, and Africa, fertilizer trees are increasingly being planted in association with improved grasses to increase carrying capacity and/or enhance the productivity of grazing cattle. In high-elevation areas of Centra1 America and the Andean region, alders are prominent components of such systems. For example, in Costa Rica, alder stands in pasture grasses cover over 50 000 ha (Kass *et al.*, 1997), whereas the drier espinales of Chile (2 million ha), Bolivia, and Argentina are dominated by *Vachellia* (*Acacia*) *caven* (Muñoz *et al.*, 2007). Similarly, in the over grazed, semi arid chaco of Argentina, Bolivia, and Paraguay (more than 1.2 million km^2) fertilizer trees in the legume genera *Vachellia* and *Acaciella* (formerly *Acacia*), *Leucaena*, *Mimosa*, *Prosopis*, *Pithecellobium*, and *Sesbania* provide N for grass growth and browse (Abril and Bucher, 2001; Muñoz *et al.*, 2007). In the more intensively managed areas in Brazil, Venezuela, Colombia, Mexico, parts of Central America, and the Caribbean, trees such as leucaena are planted in pasture or protein banks (Argel *et al.*, 1998). In Southeast Asia, leucaena and gliricidia are widely used in silvopastures. In Indonesia alone leucaena occurs in >79 000 ha of pasture land (Shelton *et al.*, 2005). In Queensland in Australia >100 000 ha of leucaena in pastures provides valuable forage for large-scale beef production (Shelton *et al.*, 2005). In Western Australia, >50 000 ha of tagasaste is grown in wide-spaced alleys or dense plantations to both provide fodder and reduce salinity by lowering the water table (Lefroy *et al.*, 1992). These are used as the sole source of feed during seasonal periods of nutritional shortage even on commercial farms.

In the parklands and in African savannahs, trees act as 'islands of fertility,' and grass growing under the canopy has better quality and yield than in the open areas (Treydte *et al.*, 2007). For example, grass productivity under faidherbia and parkia canopies was two to six times higher than in open areas in West African parklands (Boffa, 1999). Similarly, in Kenya grass productivity under acacia (now *Vachellia tortilis*) canopies was 1.5–2.3 times higher than outside the tree canopies (Weltzin and Coughenour, 1990). At Pakchong in Thailand, dry matter yield over 840 days was 30–41.5 Mg ha^{-1} in a mixture of grass and leucaena compared to 25–36.8 Mg ha^{-1} in grass alone (Tudsri *et al.*, 2002). Similarly, at Turrialba in Costa Rica, production of star grass was 16.9 Mg ha^{-1} year^{-1} with Erythrina compared to 11.7 Mg ha^{-1} year^{-1} in grass monoculture (Kass *et al.*, 1997).

In the parklands in the Sahel, pods of faidherbia provide a valuable source of dry season fodder. Parkia, locally called Néré, is also a valuable source of fodder in the Sahel, where its branches are lopped by farmers and fed to livestock in the dry season when grass is scarce. Supply of protein, which is the most important nutrient for cattle production on rangelands, can also be improved through fodder supplements from the legume genera *Acacia*, *Vachellia* (*Acacia*), *Leucaena*, etc. (Lefroy *et al.*, 1992; Mapiye *et al.*, 2011). As a result, meat and milk production is significantly improved. An analysis of results from experiments in Latin America and Australia indicated >70% increase in live weight gain and beef production using leucaena pastures (Jones, 1994).

Trade-offs

Under certain circumstances, the benefits of fertilizer trees could be offset by tree-crop competition for light, nutrients and other resources, soil acidification, or gaseous emissions

(Dick *et al.*, 2006). For example, root competition between trees and crops is a major problem, especially where fast-growing tree species are used without knowledge of optimum planting densities and management requirements. In a study on root development in a cassava-based cropping system in southern Bénin, Lose *et al.* (2003) compared annually planted pigeon pea alleys, perennial alleys, and blocks of gliricidia, flemingia, parkia, and millettia mixture. Annual alleys of pigeon pea had less interference with cassava, whereas block arrangement of the tree mixtures had detrimental effects on the cassava growth in the adjacent rows (Lose *et al.*, 2003). Even with intimate mixtures, competition may not be a problem under optimum tree densities and appropriate management such as pruning, lopping, and coppicing. Pruning offers one of the most direct and adaptable methods of controlling competition. Pruning intervals and intensities can be modified to regulate above- and below-ground competition and to match various production goals. For example, deleteriously competition for water did not exist in gliricidia-maize-pigeon pea intercropping when gliricidia was pruned before and during the cropping season in southern Malawi (Chirwa *et al.*, 2007). Water use studies in southern Africa also show minimal or no competition for moisture between the tree and crops. However, these studies have mostly been restricted to areas with relatively high rainfall (>900 mm) in normal years. In drier areas, competition may be severe.

Agroforestry has great potential for optimizing nutrient cycling and managing soil acidity under appropriate management. However, continuous removal of plant biomass (depending on ash alkalinity) may result in soil acidification. The amount of acidity generated by product removal is equal to the ash alkalinity carried by the product. If the bulk of the leguminous plant biomass is allowed to decompose on site after harvest, then the ash alkalinity is released and soil acidification minimized (Wong *et al.*, 2002). Management of soil acidification under legumes in low-input agroecosystems should therefore minimize the removal of biomass from the site of production and nitrate leaching. Localized acidification may be beneficial in circumstances where alkalinity accumulates down in the soil profile or in localized parts of the landscape. In these circumstances, the use of acidifying legume allows the alkalinity to be accessed and made available in the form of biomass with high ash alkalinity. The acid-ameliorating effect of this biomass can then be used in more acid parts of the landscape or in the more acid top soil. Using low-acidifying fertilizer tree species (provenances) may also reduce the risk of acidification. High genotypic variability within tropical legumes allows selection of genotypes.

Some of the N from legume biomass not taken up by plants and microbes in the soil can contribute to N_2O emissions (Chikowo *et al.*, 2004; Hall *et al.*, 2006), especially after rainfall events. As N addition rates progressively increase beyond the capacity of soil microbes to utilize N, the rate of N_2O production would slow down and finally reach steady state; under this stage, soil C availability would presumably control N_2O production and emission (Dong-Gill *et al.*, 2012). In a semi arid condition in Mali, Hall *et al.* (2006) found six times more N_2O emission from gliricidia plots than from continuous cultivation of sorghum without fertilizer. In a wet tropical soil, Seneviratne and Van Holm (1998) found over 5900 times more N_2O emission from soil without mulch than from plots that received gliricidia mulch. In the same experiment, N_2O emission from urea fertilizer was over 25 000 times higher than from plots that received gliricidia mulch (Seneviratne and Van Holm, 1998).

Conclusions

This review suggests that diversification of agro-ecosystems with fertilizer trees can optimize indigenous soil N supply and increase productivity of the land. Fertilizer trees have an added advantage: ensuring a multifunctional agriculture that provides timber, fodder, shade, soil improvement, and watershed management. Unlike synthetic N sources, fertilizer trees ensure greater internal nutrient recycling and water availability, thus contributing to greater nutrient use efficiency. Therefore, they can make a major contribution to sustainable agriculture by minimizing external inputs, particularly N fertilizers, increasing resource and land use efficiency, and slowing down erosion. The savings on synthetic fertilizer costs and GHG mitigation potential could also be substantial. Unlike synthetic fertilizers, fertilizer trees may play a significant role in reducing N leaching, which is particularly important during periods of reduced ground cover by herbaceous plants, such as between cropping seasons. The advantage of organic inputs over synthetic fertilizers is that much of the N from organic inputs not used by the crop is usually incorporated into various SOM pools, or assimilated by the associated trees, thus remaining in the system for other uses. N from inorganic pools not taken by the crop is subjected to higher levels of leaching and denitrification. Thus, the accumulation of N in SOM pools over time is more sustainable compared to synthetic N fertilizer, which releases nutrients rapidly. The potential of inorganic fertilizers to ameliorate the physical and biological degradation of poorly buffered soils is limited. Synthetic fertilizers, however, will remain a necessary input to agriculture to feed the increasing human population. Therefore, the focus of this article is not just whether fertilizer trees are better or worse than mineral fertilizers, because both play an important (and complementary) role in food production. The authors strongly believe that smallholder farmers would benefit if development planners were to emphasize the merits of different fertility replenishment approaches and take advantage of the synergy between fertilizer trees and mineral fertilizers rather than focusing on the 'organic versus inorganic' debate.

Although the rate of adoption of fertilizer trees has been lower than anticipated in many regions of the world, there have been notable successes in other parts. In the traditional production systems, the adoption of fertilizer trees has been driven by local tradition, economic factors, and land ownership. These traditional systems are being degraded and losing their productivity, but they may be a source of inspiration in the design of new land management practices where fertilizer trees can play a greater role in increasing food, forage, and fibre production. However, a longer-term vision and significant investment in research and development are needed. Screening of candidate tree species and development of innovations appropriate to specific conditions are important where these do not exist.

Where appropriate innovations already exist, barriers to adoption and risks that the adoption presents need to be identified.

Glossary

Agroforestry The cultivation of trees and crops in interacting combinations.
Alley farming A method of planting, in which rows of a crop are sown between rows or hedges of nitrogen-fixing plants, the roots of which enrich the soil.
Climate change mitigation Actions to limit the magnitude and rate of long-term climate change. Climate change mitigation generally involves reductions in human emissions of greenhouse gases.
Germplasm A collection of genetic resources for a plant, often stored as a seed collection.
Ideotypes Characteristics of model trees for maximizing economic yield in a particular environment for producing well-defined end products.
Legume A plant in the family Leguminosae. Legumes are notable in that most of them have symbiotic nitrogen-fixing bacteria in structures called root nodules that enrich the soil.

Introduction

Livestock are key components of farming systems throughout the world. Although livestock are often associated with wealth in many countries, approximately 1 billion head of livestock are held by more than 600 million poor smallholders, comprising approximately 70% of the world's rural poor (IFAD, 2004).

Low quality and quantity of feeds are major constraints limiting animal productivity. Feeding livestock has become particularly problematic in the developing world because of rising population growth increasing the demand for livestock products. In both developing and developed countries, the supply of livestock feed has become more scarce because of diminishing land availability due to the reduction in the quantity and quality of rangeland and natural grasslands. Changing cropping patterns, such as the recent increase in the area under crops for biofuels, further exacerbates feed availability (FAO, 2001; Ayantunde *et al.*, 2005; IFPRI, 2008).

Fodder trees and shrubs (the terms trees and shrubs are used interchangeably) are both old and new solutions to feed problems. They can be characterized as 'old' solutions because farmers have fed tree foliage to their livestock for centuries, using wild browse or trees that grow naturally on their farms (Le Houérou, 1980). They can be considered as 'new' solutions in that in recent years, there have been significant movements of germplasm and increased cultivation of fodder shrubs in many areas of the world. Moreover, nearly all fodder trees can be considered to be multipurpose, in that they provide many benefits to the farmer, the farming system, and the environment (**Table 1**; Shelton, 2005).

This article reviews the role of fodder trees in agroforestry systems in which trees and crops are deliberately grown in interacting combinations (Nair *et al.*, 2004). Thus, the many rangeland or forest systems in which pastoralists rely on wild fodder trees, or systems in which fodder trees are grown in monocropped plantations is not reviewed. As in many other agroforestry systems, fodder trees can interact with adjacent crops or enterprises; for example, competing for moisture, light, and soil nutrients or for farmers' scarce resources: land, labor, and capital.

First the main fodder tree species grown in different parts of the world are introduced. Next, practices for growing fodder trees including seeds and tree establishment, tree management, harvesting, and animal productivity are assessed. Finally, benefits and impacts and present challenges for enhancing the contributions of fodder shrubs to improved productivity, farm intensification, and livelihoods are reviewed.

Two key limitations of this review are required to be mentioned here. First, the authors were greatly restricted by the fact that they only consulted publications in English. Regions, such as Latin America, Francophone West Africa, and East and Southeast Asia are thus underrepresented. Second, many of the references do not say whether the fodder trees they discuss are part of agroforestry systems, that is, either planted or deliberately retained, or are wild browse. As this article focuses on fodder trees in agroforestry systems, the authors have not included references to fodder trees where their origin/location is not clear.

Fodder Tree Species

Eleven of the most widely planted fodder tree species are depicted in **Table 2**. There is a considerable variation in the adaptation of the leading species to different environments. All of the species listed are grown in the humid and subhumid tropics; a few such as *Gliricidia sepium*, *Leucaena pallida*, and Mulberry (*Morus alba*) are also grown in the semiarid tropics. Two are also grown in cooler tropical/subtropical areas: mulberry and tree lucerne (*Chamaecytisus palmensis* also called *Chamaecytisus prolifer*). Ten of the species are legumes; the only exception is mulberry, which, though not a legume, is still high in protein. The species are adapted to different conditions, such as drought, frost, poor drainage, and soil acidity (**Table 2**). Nine are considered to be of higher feed quality, whereas three are of lower quality, based on factors such as

Table 1 The value of fodder trees in agroforestry systems

For livestock
- Valuable source of high quality, protein-rich forage for subsistence, and commercial production of livestock, including cattle, sheep, goats, rabbits, poultry, fish, and bees
- Able to supply foliage during dry periods when herbaceous species are not productive
- Being deep rooted, they are drought tolerant and thus are important components of adaptation strategies to climate change
- Living fences, around homesteads and fields
- Some species have important medicinal attributes for treating livestock health issues

For farming systems
- Source of nitrogen-rich mulch for cropping systems
- Enhance the sustainability of farming systems due to fertility enhancement, longevity, soil cover, and control of soil erosion
- Timber for trellises and stakes for climbing crops
- Source of fruit, vegetables, and medicines

For people and the environment
- Opportunity to intensify sustainable agricultural production
- Means to stabilize sloping lands against soil erosion, due to their deep-rooting habit and permanent soil cover
- Often an important source of timber, firewood, and charcoal, particularly for domestic consumption
- Habitat for wildlife
- As woody perennials, a sink for CO_2 and contributor to climate change mitigation and adaptation
- Source of cash income when sold as forage or when seed are marketed
- A means to lower water table and to limit rise in salinity

intake of digestible dry matter, presence of antinutritive compounds, and crude protein (Shelton, 2005). Shelton (2005) reports that only approximately 20 fodder tree legumes are in significant use (that is used on large numbers of farms) out of the several hundred fodder tree legume species regarded as having potential as a feed source.

There is much debate over whether to use exotic or indigenous species. Indigenous species are widely used in many farming systems; for example, there are reports of 29 indigenous fodder tree species used by farmers in Dendi and Jeldu districts, West Shewa Zone, in central Ethiopia (Kindu *et al.*, 2006), whereas in Burkina Faso, farmers were found to use 70 tree species for fodder across three land use systems (Sibiri *et al.*, 2000). Farmers in the Solma area of Nepal use more than 90 species, subspecies, and land races of trees for fodder (Thapa *et al.*, 1997). Moreover, they have considerable knowledge about their qualities. Thorne *et al.* (1999) have confirmed that Nepalese farmers' knowledge of tree fodder quality is quite consistent with the information that nutritional researchers generate from laboratory analyses. But scientists and development practitioners make relatively little use of local species; they tend to draw on the exotics, for which seed and information is readily available. Certainly, more research is needed on indigenous species in many countries to increase the knowledge base for scientists, development practitioners, and farmers. However, it seems to be common for exotic species to out-yield indigenous ones. For example, Atta-Krah *et al.* (1986) reported that a 2-year study of 22 native fodder species in Nigeria was abandoned because none were nearly as productive as *G. sepium* or *Leucaena leucocephala*.

There is considerable discussion in the literature on ideotypes, that is, characteristics of model trees for maximizing economic yield in a particular environment for producing well-defined end products (Smith, 1992; Dickman *et al.*, 1994; Leakey and Page, 2006). The discussion involves yield/quality differences between species as well as within species (between individual trees, progenies, and provenances). Characteristics of model trees vary by location and environment but some of the most frequently cited characteristics include:

- Easy establishment.
- High productivity under repeated cutting, grazing, or browsing.
- Resistance to pests and diseases.
- High seed production ability or reliable vegetative propagation.
- High production of good quality forage in terms of protein, minerals, palatability, and digestibility.
- Suitability to different environments (e.g., temperature, rainfall, soil acidity, drainage, or salinity).

Fodder Tree Practices

Niches and Planting Arrangements

In Africa, fodder trees are widely grown in some areas of the subhumid East African highlands, including Kenya, Uganda, Tanzania, and Rwanda, primarily among dairy farmers (Wambugu *et al.*, 2011). *Calliandra calothyrsus*, *Leucaena diversifolia*, *Leucaena trichandra*, and *Sesbania sesban* are the most important species. Farmers plant the trees in neglected niches, such as around the homestead, along crop and field boundaries, and along the contour to protect the soil against erosion. This way they do not need to take scarce crop land out of production. Few farmers report that the trees reduce yields of adjacent food crops (Franzel and Wambugu, 2007), but experiments often show otherwise (Garcia-Barrios and Ong, 2004). However, experiments have shown that *Calliandra* intercropped with Napier grass (*Pennisetum purpureum*) does not depress grass yields (Nyaata *et al.*, 1998).

Farmers in other areas of Africa plant in different arrangements. In the Ethiopian highlands, *S. sesban* is the most important planted fodder tree and is generally grown in home gardens (Mekoya *et al.*, 2008). In the subhumid East and Central Mashonaland provinces of Zimbabwe, farmers plant *L. leucocephala*, *Acacia angustissima*, *L. diversifolia*, and *L. pallida* in pure stands, whereas others intercrop them with food crops or other fodder crops (Hove *et al.*, 2003; Mapiye *et al.*, 2006). In the semiarid Sahelian zone of West Africa, only small numbers of farmers plant fodder trees but many purposely allow emerging seedlings to grow on their crop lands so as to harvest fodder from them (Boffa, 1999). Most fodder trees are multipurpose, providing other products such as firewood and fruits or services such as shade and soil erosion control (**Table 1**). In many instances these 'other' products may be the tree's primary use.

Similarly, in Asia a wide range of planting arrangements is found. In Cagayan de Oro, Philippines, farmers planted their improved forage species, mainly *G. sepium*, in fodder banks, along boundaries or on contour lines (Bosma *et al.*, 2003). They used combinations of improved fodder grasses and trees to increase their incomes from livestock, including cows, buffalos, and goats for milk and meat production and rabbits and chickens solely for meat production.

In other areas of Philippines, various fodder trees are used in a conservation farming practice called sloping agricultural land technology (Devandra and Sevilla, 2002). It is a form of alley farming with crops grown in bands 4–5 m wide between contoured rows of leguminous fodder shrubs such as *C. calothyrsus*, *L. leucocephala*, *L. diversifolia*, *G. sepium*, and *Flemingia macrophylla*. Leaves are fed primarily to goats. In the islands of Nusa Tenggara Timur, Indonesia, *L. leucocephala* is the main fodder tree and is grown as a fallow rotation for maize and as a food source for tethered cows and housed goats (Piggin, 2007). In central Java, *C. calothyrsus*, *G. sepium*, and *L. leucocephala* are the most important species and are grown along field boundaries as a live fence and for feeding dairy cows (Kragten and Burgers, 2000); Chen *et al.* (1992) report the planting of fodder trees in Bangladesh on bunds, paths, and homesteads for feeding ruminants. They also note that in semiarid Pakistan, farmers plant *Acacia* spp. in rows 10–12 m apart and crops in between, until the trees mature. The trees' main use is for fuel but leaves and pods are fed to livestock.

In Latin America, Murgueitio *et al.* (2011) reported intensive sylvopastoral systems involving the planting of fodder shrubs (*Tithonia diversifolia* and *L. leucocephala*) at high densities (10 000 per ha) intercropped with pastures and timber trees. The system is used in beef cattle and dairy farms in the Tolima and Eje Cafetero regions of Columbia, in Michoacan

and San Luis Potosi areas of Mexico, and in three provinces in Panama. Shrubs and pastures are directly grazed.

Fodder shrubs also feature in agroforestry systems in some developed countries. In semiarid western Australia, *Chamaecytisus proliferus* features in two grazing systems: alley farming and plantations (Abadi *et al.*, 2003). In alley farming, *C. proliferus* is planted in lines in annual pastures, with 60 m between rows. The trees are ready for browsing in the second year and cattle graze in the fields for 6 months, every other year. In the *C. proliferus* plantations, there is an understory of annual pasture. Chriyaa (2005) reported the use of fodder trees planted at wide spacings in barley and other crop fields in Spain, Morocco, and Syria, to allow for mechanical cultivation and harvesting of the crops.

Seeds, Tree Establishment, and Management

The quality and reliability of germplasm used for planting fodder shrubs is generally low throughout the tropics. High-quality seed may be available from formal sources, such as national tree seed centers but such seed is often expensive and inaccessible to farmers. Most farmers obtain seed or other planting material (e.g., seedlings or cuttings) from local sources, without any information of provenance origins and quality or the importance of genetic diversity.

A key problem characterizing most new introductions of fodder trees to areas has been the narrow genetic base of the source of seed (often only a single or very few trees). The result is that the germplasm in the most widespread use is often of inferior quality. For example, Stewart *et al.* (1996) reported that the introduction of *G. sepium* from Trinidad into Sri Lanka was based on seed from a single tree. The lack of genetic diversity in many such introduced populations leaves them highly susceptible to damage from pests and diseases and inbreeding depression lowering yield.

Lillesø *et al.* (2011) claimed that lessons from the evolution of smallholder crop seed delivery systems indicate that a commercial, decentralized model holds most promise for sustainability in promoting smallholder agroforestry systems. However, current emphasis in agroforestry is often on government and nongovernmental organization (NGO) models of delivery, which hinder the development of a commercial, decentralized system. Graudal and Lillesø (2007) reported that an efficient seed and seedling supply is only likely to be achieved if considered as part of a commercial commodity chain in a market that encourages the operation of small, competitive seed and seedling retailers. They also warn of severe market distortions caused by free seed, which is often made available by NGOs and projects, which suppresses the emergence of private sector suppliers.

In the highlands of East Africa, fodder shrub seeds are planted in nurseries, either bare-rooted or in polythene pots, and then transplanted on farm 3 months later at the onset of the rains. Others plant seed directly in their fields. An evaluation of bare-rooted *Calliandra* seedlings in western Kenya reported 34% higher survival rates than direct seeding but the cost per surviving seedling was 24% higher, due to nursery labor costs (Swinkels, 1994). Bare-rooted seedlings cost less to produce than potted seedlings but are more susceptible to drought after transplanting. The choice among alternative techniques depends on the species involved, the available resources and farmers' skills.

In the East African highlands, trees are first pruned 9–12 months after transplanting to a height of approximately 80 cm. They are pruned approximately 4–5 times per year and generally kept at a height of below 1 m, in order to minimize the effect on adjacent crops.

Much less is known about the farmer-managed natural regeneration of fodder trees and how these trees are managed once mature. In an area of eastern Kenya ranging from subhumid to semiarid, researchers identified 160 such species that farmers used for fodder. Farmers' most preferred species were *Triumfetta tomentosa*, *Aspilia mossambicensis*, and *Melia volkensii*. Among the 15 that farmers ranked highest in importance, only one, *Commiphora zimmmermanii*, was planted and its main use appeared to be as a live fence. Most were scattered in crop land. Harvesting methods varied included coppicing, pruning branches, cutting soft twigs only, or allowing animals to browse (Roothaert and Franzel, 2001).

Fodder Yields

Yields of fodder trees depend on several factors including variety, soil and light characteristics, tree density, moisture availability, and harvesting management (e.g., cutting intensity and frequency) (Chen *et al.*, 1992; Smith, 1992). Little information is available on the yield of fodder trees and most available data are from experimental rather than farm conditions. *Calliandra* yields 1.5 kg dry matter per tree per year on farms in central Kenya, grown in hedges pruned at 0.6–1 m height, five times per year (Patterson *et al.*, 1998; Wambugu *et al.*, 2011). In Zimbabwe, where many farmers plant in pure stands, *Calliandra* yields range from 2.5 to 5.6 t ha^{-1} $year^{-1}$ and *A. angustissima*, *L. leucocephala*, and *G. sepium* produce more than 3 t ha^{-1} $year^{-1}$ when cut a single time at the end of the wet season (Hove *et al.*, 2003). In the semiarid areas around Segou, Mali, *G. sepium* yields 2 t ha^{-1} $year^{-1}$ and *Pterocarpus* spp. yields 0.5 t ha^{-1} $year^{-1}$. Mulberry yields up to 20 t ha^{-1} $year^{-1}$ (dry leaves) in Tanzania and 45 t ha^{-1} $year^{-1}$ (total yield) in Costa Rica (Sanchez, 2000).

In Indonesia, Devandra and Sevilla (2002) reported dry matter yields of *S. grandiflora* at 215–412 g per tree or 9–11 t ha^{-1} and those of *G. sepium* at 1–1476 g per tree or 13–27 t ha^{-1}. *Calliandra* yields range from 0.8 to 3.3 kg per tree, and *L. leucocephala*, at 15.4 t ha^{-1}. Chen *et al.* (1992) reported dry weight leaf yields of *L. leucocephala* in Asia and the Pacific ranging from 4 to 15 t ha^{-1} $year^{-1}$.

Animal Productivity

The feed value of a forage is a function of its nutrient content and digestibility, its palatability and the associative effects of other feeds (Smith, 1992). These factors interact among themselves and with the health and breed of the animal to determine the effective feed value of the material.

On average, fodder trees are richer in protein than tropical grasses, such as *Panicum maximum* or *Pe. purpureum*. This is

especially true during the dry season, when crude protein content of many tropical grasses drops below the minimum 6% required for maintenance. In contrast, many fodder trees remain green with high protein content, often in the range of 15–24% (Smith, 1992). Fodder shrubs can be used to improve quality of crop residues and by-products (Larbi *et al.*, 1993).

The nutritive value of fodder trees cannot be accurately determined without indication of their digestibility. Leaves of fodder trees degrade fairly well and rapidly but digestibility values may not be a good indicator of the feed value of fodder because of such factors as metabolic attributes, which may reduce intake or bind nutrients. Because of such attributes, it has been generally recommended that fodder tree leaves should be less than 30% of a cow's diet and for some tree species, less than 15%. Evaluations of feed value should also be complemented by feeding trials and, if possible, ones under or simulating farmer management and conditions (Smith, 1992).

Considerable evidence on fodder shrubs' effect on milk yields comes from research on *Calliandra* in East Africa. A farmer in East Africa needs approxiamtely 500 *Calliandra* trees to feed a dairy cow throughout the year at a rate of 2 kg dry matter per day. One kilogram of dried *Calliandra* (24% crude protein and digestibility of 60% when fed fresh) has about the same amount of digestible protein as 1 kg of dairy meal (16% crude protein and 80% digestibility) (Roothaert *et al.*, 2003). Two kilograms of dried *Calliandra* provide an effective protein supplement to the basal feed of Napier grass and crop residues, according to on-farm feeding trials from Embu District, Kenya (Paterson *et al.*, 1998) and Masaka District, Uganda (Kabirizi *et al.*, 2006). Under farmers' management, milk production increased by 0.6–0.75 kg milk per kg dried *Calliandra*. Surveys also reported farmers' estimates of the milk response to *Calliandra* feedings. In one, farmers estimated that the mean response was 0.80 kg milk per kg dry *Calliandra* (Franzel and Wambugu, 2007) slightly above the range of the findings from the on-farm trials. In the other, in which farmers reported amounts of tree fodder fed and milk produced, the response was 0.35 kg milk per kg dried *Calliandra* (Place *et al.*, 2009). One of the trials also investigated the effect of *Calliandra* on butter fat and found a positive, but not statistically significant effect (Paterson *et al.*, 1999). A study in Kenya showed that intake of Napier grass increased due to supplementation with *L. leucocephala* leaves, which resulted in significant increases in milk yields. Milk yield increased over control treatment by 20% (Muinga *et al.*, 1992). *Sesbania sesban* has shown a similar effect on feed intake when used as supplement for sheep in Ethiopia (Khalili *et al.*, 1994).

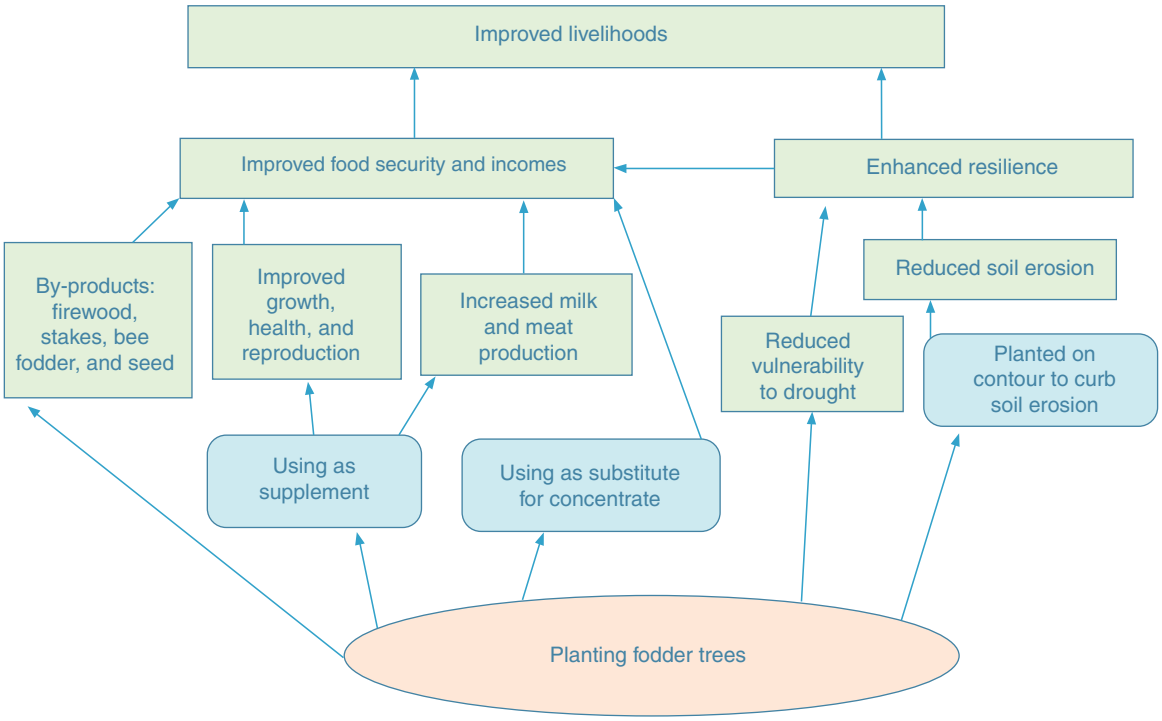
Only one study was found assessing the effect of fodder trees on nondairy cattle in Africa, which confirmed the effectiveness of *L. leucocephala* as a dry season supplement for grazing steers in semiarid western Tanzania (Kakengi *et al.*, 2001).

Dairy goats are an important and rapidly growing smallholder enterprise in East Africa. Many farmers grow fodder trees to feed their goats (Place *et al.*, 2009) and studies confirm their significant impact on milk yields (Kirurio *et al.*, 1999), Niang *et al.*, 1996). Ewes supplemented with *S. sesban* in Ethiopia showed a 13% increase in milk production over ewes supplemented with concentrates (Mekoya, 2008). Numerous experiments have confirmed the effectiveness of fodder trees in increasing the productivity of sheep and goats. Sheep gained 79–90 g day^{-1} in live weight from being fed *Calliandra* in Kenya (Kirurio *et al.*, 1999; Niang *et al.*, 1996). Concerning dairy goats, supplementation with *Mimosa scabrella* in the highlands of Rwanda enabled goats to gain 50 g day^{-1} compared with 31 g day^{-1} for grass alone. Six other tree species also increased body weight (Niang *et al.*, 1996).

Benefits and Impacts

Fodder trees contribute to improved livelihoods in various ways, as discussed below (**Figure 1**).

Increased Production and Income From Cattle



In Cagayan de Oro, Philippines, fodder trees were the most important feed source during the dry season and ranked second to fodder grasses during the wet season. The profitability of the combined and improved fodder species (trees, grasses, and herbaceous legumes) was assessed and they were found to increase net incomes from livestock production from US$68 to US$503 per household. The forages increased crop production by a further US$22.50, based on farmer estimates of increased crop yields. Further, the improved forages reduced farm labor, especially for herding and tethering, valued at US$36 per year (Bosma *et al.*, 2003).

Considerable evidence on income from fodder shrubs also involves *Calliandra*. Farmers use it both as a supplement to increase milk production and as a substitute for dairy meal. It can be fed fresh or stored and fed dry, which does not significantly reduce nutritive quality (Tuwei *et al.*, 2003). Net returns in 2002 and 2003 ranged from US$62 to US$122 per year across four sites in Kenya and Uganda for a farmer with 500 trees. Farmers' actual numbers of trees were usually fewer, ranging from means of 130 trees per farm in western Kenya to 560 trees per farm in southwestern Uganda, resulting in net returns ranging from US$30 to US$114 per year (Wambugu *et al.*, 2006). Net returns varied across sites primarily because of differences in numbers of trees and in milk prices. An estimate in 2009 found mean net returns to be US$35 per year in central Kenya (Place *et al.*, 2009). The lower amount was primarily due to lower estimates of amounts fed and response of milk yields.

An economic analysis from Chikwaka District, Zimbabwe, found that the use of fodder trees (*L. leucocephala*, *A. angustissima*, *L. diversifolia*, and *L. pallida*) in smallholder dairy had gross margins of US$13–334 and benefit–cost ratios of 1.12–3.03. The margins and ratios varied depending mainly on the amount of tree fodder fed; higher use led to higher returns (Moyo and Ayuk, 2001).

In semiarid western Australia, cattle graze on annual grasses (*Brassica* spp.) and tree legumes (*C. proliferus*) in two grazing systems: alley farming and plantations (Abadi *et al.*, 2003).

These systems earn a net present value (the present value of a stream of future costs and benefits occurring over a period of years) of approximately US$303 per ha (using a discount rate of 7%) and an annual equivalent return of US$24 per ha. In alley farming, *C. palmensis* is planted in 6 m wide belts, with

Food security, income, and livelihoods are grouped together in this diagram but contributing to one does not necessarily contribute to the other, as when an increase of cash income is taken by the male head of household for his own use.

Figure 1 Principal ways that fodder trees contribute to improved food security, incomes, and livelihoods. Reproduced from Franzel, S., Carsan, S., Lukuyu, B., Sinja, J., Wambugu, C., 2014. Fodder trees for improving livestock productivity and smallholder livelihoods in Africa. Current Opinion in Environmental Sustainability 6, 98–103.

60 m between rows. The trees are ready for browsing in the second year and cattle graze in the fields for 6 months, every other year. In the *C. palmensis* plantations, there is an understory of annual pasture. Compared to annual pastures, *C. palmensis* alley farming and plantations increase net present values by US$65 and US$124 per ha, respectively. Incremental annual equivalent returns are US$5 and US$10, respectively (Abadi *et al.*, 2003). These numbers appear low but as ranching is extensive, a small per-hectare increment can add substantially to farm income.

Increased Production and Income from Small Ruminants

The only economic analysis involving fodder trees and small ruminants in Africa is from Segou, Mali. In on-farm trials, *G. sepium* and *Pterocarpus* spp. were evaluated on their contributions to sheep growth and on the time they saved farmers from having to collect fodder off the farm. Fodder shrubs were found to be profitable only under conditions where alternative options were expensive (Hamer *et al.*, 2007). Although not a formal economic analysis, a study from Ethiopia found that farmers in three land use systems made widespread use of *S. sesban* for feeding sheep, and had strong positive perceptions of the tree's effect on weight gain and reproductive performance in two of them (Hess *et al.*, 2006; Mekoya *et al.*, 2008).

Other Benefits as Feeds

Few studies report on the marketing of fodder tree leaves or their use in commercial feeds. In the Tanga area of northeastern Tanzania, *L. leucocephala* leaf meal is widely marketed, primarily to urban dairy producers. Most is from wild populations but some is cultivated on farms. Leaf meal is also an ingredient of one of the country's major mineral supplements (Franzel *et al.*, 2007). Analyses of the use of leaf meal in mineral blocks for sheep in Nigeria have been conducted but use at the farm level is not reported (Aye and Adegun, 2010). *Leucaena leucocephala* leaf meal is widely sold along road sides in eastern Thailand (S. Franzel, pers. comm.).

Sonaiya and Swan (2004) reported that tree leaves are an important component of poultry feeds in many countries and specifically recommend *Leucaena* spp., *Calliandra* spp., and neem (*Azadirachta indica*). They report on a study from Pakistan that found that a 20% ration of fresh neem leaves increases feed intake and egg production in layers. Farmers in East Africa also report feeding tree biomass to poultry (primarily to make yolks brighter yellow, which increases egg prices), rabbits, and fish (Place *et al.*, 2009).

The above analyses do not take into account many other benefits of fodder shrubs as cited by farmers in Kenya and Uganda (**Table 3**). These include the provision of products (firewood, stakes, bee forage, and seeds, which are sometimes sold) and services (fencing, soil fertility improvement, soil

Table 3 Benefits of fodder shrubs, other than inceased milk production, according to dairy farmers in two African farming systems

Type of benefit	*Percentage of farmers mentioning in*	
	Embu area, Kenya (N = 60)	*Kabale area, Uganda (N = 93)*
Firewood	50	72
Soil fertility improvement	48	72
Improvement in animal health	38	5
Soil erosion control	18	20
Improved creaminess of milk (increase in butter fat)	18	6
Fencing	18	76
Revenue from sale of seedlings	13	9
Stakes	9	70

Note: Percentages sum to greater than 100 because many farmers mentioned more than one benefit.
Source: Reproduced from Franzel, S., Carsan, S., Lukuyu, B., Sinja, J., Wambugu, C., 2014. Fodder trees for improving livestock productivity and smallholder livelihoods in Africa. Current Opinion in Environmental Sustainability 6, 98–103.

erosion control, and improvement in animal health and reproduction) (Franzel and Wambugu, 2007). Few estimates of the quantities and values of these products and services were found. In Kenya, hedges combining Napier grass and *Calliandra* or *L. trichandra* reduced runoff and soil erosion while not reducing adjacent maize yields (Angima *et al.*, 2002; Mutegi *et al.*, 2008). Fodder trees can also help farmers adapt to and mitigate climate change (Badege *et al.*, 2013). For adaptation, they are deep rooted, resistant to drought, and maintain high protein levels during the dry season, when high-quality feed is scarce (Wambugu *et al.*, 2011). For mitigation, fodder trees improve livestock productivity, which helps reduce methane emissions per unit of output and helps reduce carbon emissions by substituting for commercially manufactured concentrates. But no studies were found that explicitly quantify the contributions of fodder trees to climate change adaptation or mitigation.

Gender Considerations

There is widespread recognition that women are disadvantaged in the agricultural sector of many developing countries (World Bank, 2012; Kiptot and Franzel, 2012). This has led to research and development initiatives to try to redress the imbalance. Some of these initiatives have deliberately targeted women groups to impart knowledge and technology to them, to ensure that extension activities address different interest groups, holding separate meetings for men and women and training more women extension officers, particularly to serve communities that have strong traditions that prohibit male extension officers from interacting with women farmers. Research on gender and fodder trees has shown that women in Africa can benefit considerably from planting fodder shrubs, for several reasons (Kiptot and Franzel, 2011). First, women in many countries are responsible for collecting fodder off the farm. Growing fodder on farms can thus reduce their time spent searching for fodder, freeing up labor for attending to their families or engaging in other productive enterprises. Second, because women are often cash-constrained, they are unable to purchase concentrates for feeding their livestock. Fodder shrubs can provide protein at a much lower cost than purchased concentrates. Third, female households head plant fodder shrubs at about the same rate as male heads of households and are able to manage the trees as effectively (Kiptot and Franzel, 2011). Finally, research has shown that women in East Africa have access to cash earned from dairy. In Tanzania and Uganda, women managed and controlled 39.8% of the income from milk, and 70.4% of the income if sold in informal markets (Njuki *et al.*, 2011). Planting fodder shrubs will increase animal productivity and hence the income that they access from milk.

Key Challenges for Enhancing Fodder Trees' Benefits

Three key constraints limiting the uptake and benefits of fodder shrubs are as follows:

Species diversification: There is a lack of species appropriate to different agroecological zones, particularly high altitude (>2000 m) and semiarid zones. In humid and subhumid zones, species are needed that provide more nutritious biomass than some of the species in widespread use, such as *Calliandra*, and that are resistant to psylids (*Heteropsylla cubana*), jumping plant lice, which prevent farmers from planting *L. leucocephala*. More research is also needed on indigenous species. Efforts should be made to integrate the huge amount of indigenous knowledge about indigenous species with scientific methods to screening and testing them.

Lack of functioning seed supply systems: Emerging seed markets have facilitated adoption in some countries (e.g., Kenya; Acharya *et al.*, 2010) but are yet to emerge in other countries. Main constraints include policies of government seed centers, plant health regulatory agencies, and NGOs that distribute free seed (Franzel and Wambugu, 2007). Decentralized, commercial models provide greater potential than government or NGO-led models (Lillesø *et al.*, 2011).

Weak extension support: Although fodder trees require relatively little land, labor, or capital, they are a knowledge-intensive practice as farmers need to acquire new skills such as nursery establishment, tree pruning, and seed collection. As weak as extension systems are in most developing countries, agroforestry extension is nearly nonexistent. Promoting innovative approaches such as farmer to farmer extension, civil

society campaigns, and facilitative policies can help promote widespread adoption (Wambugu *et al.*, 2011).

Glossary

Competition Occurs when trees exploit the same resources as crops.
Complementarity Occurs when trees acquire resources that crops cannot acquire.
Hydraulic lift Upward transfer of water through roots from wetter soil at depth to surface horizons.
Leafing phenology Seasonal trend in leaf flushing and leaf drop.
Resource capture The capture of essential growth resources (light, water, and nutrients) by plants.
Sap flow Measurement of water movement in stems or roots using heat as a tracer.
Water-use efficiency The ratio of the total amount of biomass produced to crop water use.

Introduction

In addition to their social and economic value, forests and agroforestry (AF) have been widely promoted as a viable solution to overcome the loss of ecosystem functions associated with the conversion of natural landscapes for human use (Jose, 2009). AF systems vary in the density and configuration of trees in farming landscapes from a few scattered trees or line plantings to dense and complex agroforests. However, the relationship between tree cover and water supply is not straightforward and forest/agriculture policies are often at odds with scientific understanding. In the tropics, forest/farming and water policies were often based on the assumption that tree-covered landscapes are the most appropriate way to maximize water yield, regulate seasonal flows, and ensure high water quality under all hydrological and ecological situations (Calder *et al.*, 2007). According to this assumption, conserving or extending tree cover in upstream watersheds is the most effective way to enhance water availability for agricultural, industrial, and domestic use and prevent floods in downstream areas. Various national agencies, often with international cofunding, are spending vast sums of money on tree planting and soil conservation efforts based on the belief that 'more trees mean more water'.

However, forest hydrology research in the 1980s and 1990s suggests a different picture and has implications for AF. Although the important role of upstream forest cover in ensuring the delivery of high-quality water has been confirmed, earlier assumptions regarding its benefits in terms of providing more temporally dispersed downstream seasonal and annual flows were generally overestimated (Bruijnzeel, 2004). Furthermore, in arid and semiarid ecosystems, forests and savannah woodlands do not provide the best land cover to increase downstream water yield. It is now recognized that the protective role of forest cover in regulating extreme flow in tropical ecosystems has been overestimated, particularly in connection with major events such as floods affecting large-scale watersheds or river basins (FAO and CIFOR, 2005).

According to van Noordwijk *et al.* (2006), current approaches to AF solutions to watershed problems require four basic steps: (1) diagnosis of problems at the watershed scale, (2) comparing land-use options on the basis of buffering functions, (3) modeling biophysical degradation and rehabilitation processes in the analysis of tradeoffs between profitability and watershed functions, and (4) negotiations between stakeholders of solutions based on tradeoffs. They concluded that the criteria and indicators of watershed functions such as the timing and quality of river flows are influenced by a combination of effects, including the green and brown cover provided by plant canopies and surface litter layers, soil surface properties and structure, and the landscape drainage network. Using data from two contrasting watersheds at Mae Chaem (1500 mm annual rainfall) in Northern Thailand and Way Besai (2500 mm rainfall) in Lampung, Indonesia, they found that the changes in land cover have relatively little effect on low river flow. Instead, they showed that changes in soil structure tend to dominate long-term opportunities to keep watersheds productive, as well as providing quality water at the desired time.

Impact of Trees on Water Balance

Water balance represents the balance between inputs from rainfall and/or irrigation and the sum of evapotranspiration, stream flow, and losses to groundwater. Contour-planted hedgerows are frequently recommended for sloping land in the tropics because they increase infiltration and improve soil conservation (Young, 1997). An estimated 500 million people practice unsustainable forms of subsistence agriculture on marginal hillsides, exacerbating the problems of erosion. To understand how trees influence the hydrology of individual

 doi:10.1016/B978-0-444-52512-3.00028-0

fields or farms, it is necessary to understand the processes involved. To begin it is examined how the introduction of trees may improve on-farm water balance by reducing losses. Evidence from analyses of farmers' fields around the world shows that, on average, only 30% of rainfall is used for crop growth and emitted to the atmosphere as transpiration (Rockstrom *et al.*, 2007); the remainder is lost as runoff, evaporation and drainage. In humid zones, rainfall greatly exceeds that required to sustain crop transpiration and the main losses are due to runoff and drainage. In arid and semiarid areas, transpiration ranges between 5% and 40% of rainfall, suggesting that there is ample scope to increase agricultural productivity because water is wasted. Although poor agricultural production is often attributed to low rainfall, other factors such as low soil fertility or poor land management are often even more important. In the case of AF, integration of trees can theoretically increase productive use of rainfall by reducing runoff, drainage and soil evaporation by maintaining partial leaf cover following crop harvest.

Perhaps the best example of the effectiveness of this approach to water management in farming systems is in Southern Australia, where trees are used to manage excess water that has accumulated in rising water tables since the native perennial vegetation was cleared. This problem exacerbates salinization, a major constraint to agriculture in this area. The hypothesis is that the introduction of trees creates a much higher year-round leaf area than annual cropping systems, thereby combating secondary salinization by increasing the extraction of groundwater and enhancing drainage below the crop rooting zone (Lefroy and Stirzaker, 1999). Evidence for young eucalypts or tagasaste fodder hedgerows has shown that their roots remove water from below the crop rooting zone between the tree belts. Furthermore, strategic placement of trees in the landscape minimizes the land area required to be planted to induce the desired effect on local hydrology (Brooksbank *et al.*, 2011a). Eucalyptus is renowned for its high water consumption, competitiveness, fire risk and suppression of biodiversity, and is rarely recommended for AF. Unsurprisingly, its high productivity and demand for water are raising concerns over declining water yield in catchments in South Africa, Kenya, and India (Ong, 2003). However, despite these problems, eucalyptus is highly prized as a cash crop in countries experiencing severe deforestation such as Ethiopia, India, and China.

Although the moderating effects of forests on stream flow have been reevaluated, evapotranspiration from forests nevertheless has an important influence on rainfall. Recent work combining remote sensing data for rainfall and vegetation with atmospheric transport trajectories demonstrates that forest cover increases tropical rainfall on a regional scale, an effect which may extend for hundreds and thousands of kilometers downstream of forested areas (Spracklen *et al.*, 2012).

Complementary and Competitive Interactions for Resources

AF is known to increase overall system productivity and enhance soil structure, nutrient recycling, and sustainability, while producing timber, firewood, fruit, fodder, and green manure in addition to annual food crops (Young, 1997). However, the potential benefits depend on complex spatial and temporal interactions between the biological, physical, hydrological, and climatic components of the system; these include the tree and crop species involved, soil type, depth and fertility, quantity and distribution of rainfall, solar radiation, and air temperature and atmospheric humidity (Ong *et al.*, 2002, 2006; Lott *et al.*, 2009). A major aspect affecting the overall outcome of integrating trees in farming systems is the increasing competitiveness of trees as they establish and grow larger (Lott *et al.*, 2000a,b).

Tree roots extend to much greater lateral distances and depths than those of crops (Stone and Kalisz, 1991), thereby exploiting a much greater soil volume. There is therefore the potential for both complementarity and competition depending on the distribution and activity of tree and crop roots in the soil profile. Rooting depth is potentially unlimited in deep soils lacking impenetrable hardpans or stony horizons and the roots of some tree species may reach depths of 20–30 m in search of deepwater reserves.

Complementarity may be either spatial or temporal. Spatial complementarity occurs when trees exploit deep reserves of water and nutrients, satisfying the central tenet of AF that trees must exploit resources which crops cannot access if the system is to succeed (Cannell *et al.*, 1996). For example, stable isotope studies in Niger have shown that neem trees (*Azadirachta indica*) extracted groundwater at a depth of 6 m at Majjia Valley but not at Sadore, where the water table was too deep to be accessible (35 m; Smith *et al.*, 1997). By contrast, temporal complementarity occurs when trees make their primary demand for resources at different times to crops, for example, during the dry season after crops have been harvested. This has been illustrated in studies of hedgerow intercrops containing *Leucaena leucocephala* at Hyderabad, India, which showed that the trees continued to grow during the dry season when 20% of the annual rainfall was received (Black and Ong, 2000).

An interesting agronomic solution to achieving temporal complementarity is to use trees that are fully or partly deciduous (leafless) during the cropping season (Broadhead *et al.*, 2003a,b; Muthuri *et al.*, 2005). This complementary leafing phenology means they are less competitive than evergreen trees which utilise resources throughout the year. However, adoption of less competitive tree species may be incompatible with the objectives of farmers as they are often less productive than fast-growing trees producing economically valuable products. If farmers wish to plant more fast-growing species, management practices such as root and/or shoot pruning may be needed to control competition for below-ground resources and reduce shading of crops.

Trees Improve Infiltration of Water and Reduce Evaporation and Runoff

The use of improved fallows is an important AF practice for improving soil fertility as it avoids direct competition between

trees and crops. This is illustrated by the bench terraces used on steep hillsides in Kabale District, Southern Uganda, where repeated downslope cultivation and soil creep during heavy rain draw topsoil to the front of the terrace, exposing the infertile subsoil on the upper terrace. The upper terrace is therefore less productive, providing only 5% of the total yield when the entire terrace is planted with sole crops. However, tree fallows containing *Alnus acuminata* (alnus), *Calliandra calothyrsus* (calliandra), *Sesbania sesban* (sesbania), or a mixture of all three species planted on the upper part of the terrace produce a range of tree-based products and improve soil structure and fertility, whereas food crops such as beans and maize continue to be grown on the lower terrace (Siriri *et al.*, 2010, 2012).

In this study, measurements of soil water content (θ_w) when sesbania trees were 31–39 months old and alnus and calliandra were 37–45 months old showed that unpruned sesbania increased θ_w by 14% and 18%, respectively, on the upper terrace, where the trees were grown, and in the cropping area on the lower terrace. The equivalent increases for alnus were 15% and 9%, whereas the more competitive calliandra reduced θ_w by 3% and 15%, respectively, on the upper and lower terrace. In parallel with these effects on θ_w, soil evaporation (E_s) comprised 53% of rainfall under sole maize compared with 38%, 37%, and 29% in the *Sesbania*, *Calliandra*, and *Alnus* systems following periods of high rainfall (Siriri *et al.*, 2012). *Alnus* and, especially, *Sesbania* therefore increased the available soil moisture and reduced the proportion of unproductive rainfall. Moreover, tree fallows reduced runoff from 17% to 4% of seasonal rainfall (Siriri *et al.*, 2006). These findings suggest that *Sesbania* and *Alnus* may be integrated on smallholdings without compromising water supplies for crops, although alnus must be pruned to sustain crop yield. By contrast, although *Calliandra* reduced E_s, the water saved was absorbed by its extensive root system, depriving crops of water and suggesting that *Calliandra* fallows are inappropriate because the crop yield was reduced even after pruning (Siriri *et al.*, 2010).

In addition to accessing deep water reserves beyond the reach of annual crops, tree roots act as a safety net to capture nutrients leached from the topsoil and return these to the soil surface as litter (Rowe *et al.*, 1999). Nitrogen (N) is the most limiting nutrient for crop production in much of sub-Saharan Africa, but the high cost of inorganic fertilisers often precludes their use by poor farmers. This has increased interest in low input AF systems containing leguminous tree species whose leafy biomass provides green leaf manure (GLM) to supply N to crops (Okogun *et al.*, 2000). Crop yield is typically strongly correlated with preseason mineral N concentration (NO_3^-+NH_4^+) in the topsoil and mineralisation of organic matter following improved fallows or in mixed cropping systems containing leguminous species (Ikerra *et al.*, 1999). Application of *Gliricidia* GLM leads to almost immediate release of N, with 30% being released within 7 days and up to 60% within 24 weeks. If inorganic fertiliser is also added, *Gliricidia* GLM releases up to 60% of its N within 3 weeks and 70% within 24 weeks (Itimu, 1997; Phombeya, 1999). Significant improvements in maize yield were apparent in tree-based systems after 2 years, when approximately 3.0 t ha^{-1} of grain was obtained, which is triple that for unfertilised sole maize (Chirwa *et al.*, 2003). However, although application of GLM increased preseason soil mineral N levels, these declined rapidly during early crop growth when the plants were too small to exploit the available N (Chirwa *et al.*, 2006). In such circumstances, the presence of trees improves nutrient use efficiency by providing a safety net to capture nutrients leached from the topsoil during intense rainfall and return them to the surface horizons on which crop roots primarily depend, in a manner analogous to the hydraulic lift of water described later.

The greatest opportunity for simultaneous tropical dryland AF systems appears to be exploitation of complementary interactions between trees and crops grown for their marketable products (Ong and Leakey, 1999). Although trees provide valuable ecosystem services, these are not usually the primary reason why farmers retain, manage, or plant them. Thousands of tree species are cultivated for valuable products such as poles, fruit, fodder, firewood, and medicinal compounds, as illustrated by the World Agroforestry Centre's Database. Tradeoffs often exist between valuable tree products and the ecosystem services trees bring. For example, fast-growing eucalypts are highly prized in highly degraded countries such as Ethiopia, where they are by far the most popular tree species with farmers and attempts to introduce more benign species have been disappointing.

Species with outstanding hydrological properties and excellent complementarity of water use are often neglected by farmers. Many native tree species are ideally suited for planting with annual crops but either of low value or have slow growth rates. An exceptional case of successful avoidance of competition in simultaneous AF systems is the traditional use of *Faidherbia albida*, now a target species of the farmer-managed natural regeneration program (FMNR) in the Sahelian parklands. Its high degree of complementarity results from its unusual reverse canopy phenology as it is leafless during the cropping season and leafy during the dry season. Many authors have reported increased crop yields under *F. albida* trees (the 'albida effect'), which have been attributed to improved availability of water and essential macronutrients, particularly nitrogen and phosphorus, although the relative importance of these factors varies seasonally and depends on soil water and nutrient status at specific sites (Rhoades, 1995; Kho *et al.*, 2001).

However, the 'albida effect' would require 20–40 years to develop in Ethiopia (Poschen, 1986), a timescale well beyond the planning horizon of most farmers. Of course, it would be ideal to match valuable trees with crops so reductions in crop yields are more than offset by valuable products from the trees. One example is the *Melia volkensii*–millet system used in semiarid Kenya (Ong and Leakey, 1999). A recent approach is to promote and assist FMNR of useful trees such as *F. albida* (Garrity *et al.*, 2010). FMNR began in Niger during the 1980s due to the failure of massive conventional reforestation projects in the Sahel. An analysis of satellite imagery has revealed that 4.8 m ha of *F. albida*-dominated farmlands have spread through the Maradi and Zinder regions through this practice (Reij *et al.*, 2009). Further research is needed to understand fully how FMNR promotes rapid tree growth in Niger.

Why Tree Root Distribution Matters

Historically, much research has focused on the more visible above-ground competition between trees and crops, and in understanding the effects of tree canopies on crops resulting from shading and rainfall interception. However, below-ground competition, determined primarily by the distribution and activity of tree and crop roots, is at least as important, but much less well understood, because the required research is more difficult. Below-ground aspects of competition are invisible to farmers, who often attribute competition to shade rather than for water and nutrients. In practice, crop yield is determined by the balance between the above- and below-ground elements of competition, depending on the prevailing limiting factors for growth. Disentangling these issues is challenging.

The use of soil water by trees and crops in AF systems depends on many factors, but is optimized when use of below-ground space is maximized both spatially and temporally. This involves consideration of both the architecture and activity of tree and crop roots at different developmental stages. Annual crops and perennial grasses are relatively shallow-rooted, occupying the surface horizons where soil water content is most variable and responds rapidly to rainfall. In contrast, tree roots can extend deep below the soil surface and laterally into the crop rooting zone, well beyond the edge of the tree canopy (Stone and Kalisz, 1991; Schroth, 1998). The main structural roots of trees are long lived and provide the framework on which the fine roots (<2 mm diameter), which are active in water and nutrient acquisition, are deployed; these are short lived and their turnover makes a considerable contribution to soil carbon accumulation. Although deep tree roots can tap into ground water, evidence from sap flow studies (Brooksbank *et al.*, 2011c) indicates that trees preferentially access water from surface zones when this is available. Thus, trees usually compete with crops during the rainy season as their preexisting rooting framework provides a competitive advantage over the emerging roots of germinating crops. Though tree species vary in rooting architecture and root biomass, this is not necessarily reflected by their growth or competitiveness (Wajja-Musukwe *et al.*, 2008). An evaluation of the ratio of root number in the top 1.8 m of soil to trunk volume has shown that *Casuarina equisetifolia* and *Markhamia lutea* had significantly higher ratios than *A. acuminata*, *Maesopsis eminii*, and *Grevillea robusta*; *Casuarina* and *Maesopsis* were most competitive with crops, whereas *Markhamia* and *Grevillea* were least competitive. Tree propagation method also affects root architecture, and hence, potentially, competition (Mulatya *et al.*, 2002; Asaah *et al.*, 2010, 2012).

Several options are available to farmers to manage below-ground water resources (Schroth, 1998; Rao *et al.*, 2004). Their decisions depend on the relative value of products from trees and crops, labour supplies, and availability of soil resources. In some situations, trees and crops may be temporally segregated using rotational fallows, but in simultaneous AF systems competition can be controlled using appropriate tree/crop combinations and planting configurations, or tree management practices involving root and/or crown pruning to control water demand and zones of water uptake. An agronomic approach to achieve temporal complementarity is to use trees with complementary leafing phenology; for example, species that are fully or partly deciduous are less competitive with crops than the evergreen species that capture resources throughout the year (**Figure 1**; Broadhead *et al.*, 2003a,b; Muthuri *et al.*, 2005).

Pruning offers a direct and adaptable method of controlling competition and has been the focus of several studies in East Africa (Tefera, 2003; Rao *et al.*, 2004; Wajja-Musukwe *et al.*, 2008; Namirembe *et al.*, 2009; Siriri *et al.*, 2010, 2012). This practice enables farmers to grow the tree species they prefer by managing their growth. Crown pruning varies in intensity and ranges from removing the lower branches to raise the tree canopy to the removal of almost all branches of trees or hedgerows (pollarding). Crown pruning has the added advantage of yielding animal fodder, fuel, and small wood and provides an ongoing and flexible source of nontimber products and income before the trees are harvested. Root pruning may be achieved by tillage as the normal process of land preparation disrupts the fine roots of trees in the surface soil horizons. As these rapidly regrow, longer lasting effects can be achieved by severing all lateral roots close to the trunk with a machete or hoe at the start of the cropping season. This enforces spatial separation of tree and crop roots, but yields no direct product unless farmers are sufficiently fuel-hungry to excavate cut roots. The ease of the first cut depends on the age of the trees but, if repeated annually, the cutting of root regrowth requires little effort and is easily integrated into land preparation. Although root pruning is an attractive option in some circumstances, practitioners must be aware that, if this is incomplete, the activity of the remaining uncut lateral roots is increased so that no overall improvement in crop yield is obtained (Wajja-Musukwe *et al.*, 2008). **Figure 2** illustrates the potentially substantial beneficial effect of root pruning on crop growth: maize has attained full height adjacent to the tree on the pruned side, but in this situation of 'incomplete' pruning, the competition effect is exaggerated on the unpruned side.

The influence of pruning trees on associated crops varies between species. In the study of bench terraces in Uganda, mentioned earlier (Siriri *et al.*, 2010), in which three tree species were grown on the infertile upper third of terraces and annual crops were planted on the lower terrace, shoot pruning of trees <2 years old was sufficient to maintain crop yield, but a combination of crown and root pruning was required as trees grew larger. *Calliandra calothyrsus* was more competitive than *A. acuminata* and *S. sesban*, whereas beans (*Phaseolus vulgaris*) were more sensitive to competition than maize (*Zea mays*). Measurements of sap flow through the trunks of trees can be used to determine diurnal and longer term patterns of water use and the impact of pruning. Such studies revealed that root pruning greatly reduced diurnal water use in *G. robusta* in Kenya (**Figure 3(a)**; Anyango, 2005), and that shoot or root pruning both reduced sap flow in *Alnus* and *Sesbania*, whereas only root pruning was effective in reducing water use by *Calliandra* in Uganda (**Figure 3(b)**; Siriri, 2013).

Tefera (2003), working on boundary-planted trees (*C. equisetifolia*, *G. robusta*, *M. lutea*, and *Eucalyptus grandis*) in Kenya, observed that pruning (pollarding, root pruning, and pollarding plus root pruning) increased the survival and productivity of intercropped maize compared with unpruned

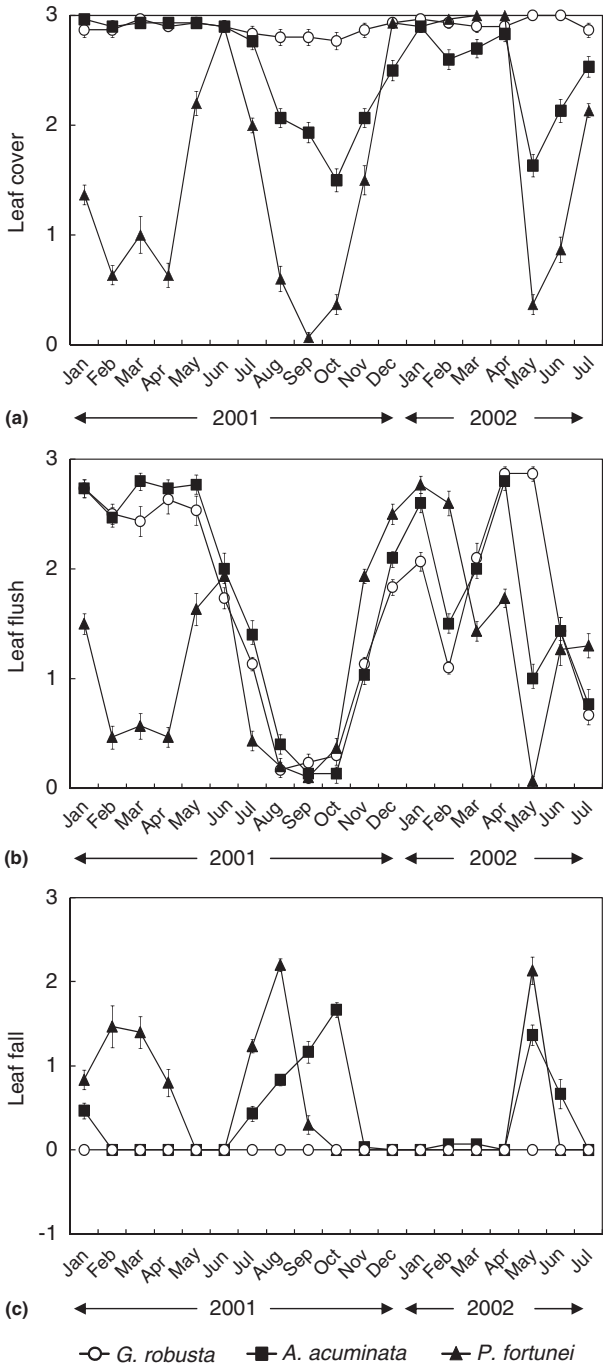

Figure 1 Time courses for (a) leaf cover, (b) leaf flush, and (c) leaf fall in *Grevillea robusta, A. acuminata,* and *Paulownia fortunei* trees at Thika, Kenya, between January 2001 and July 2001. Adapted from Muthuri, C.W., Ong, C.K., Mati, B.M., van Noordwijk, M., 2005. Modeling the effects of leafing phenology on growth and water use by selected agroforestry tree species in semi-arid Kenya. Land and Water Resources Research 4, 1–11. Vertical bars show double standard errors of the mean. Scores were ascribed using a four-point scale ranging from 0 (absent), 1 (low), 2 (intermediate) to 3 (high).

control plots, although effects varied between species (Figure 4). Two years after pruning, sap flow was lowest in pollarded *C. equisetifolia* and *G. robusta* trees and highest in

Figure 2 Influence of root pruning on one side of the *Grevillea robusta* tree row 2 years previously (far side of the tree row) on the growth of maize in Western Kenya. Note that growth was greatly reduced by competition for below-ground resources on the unpruned side of the tree row (foreground).

root-pruned trees (Figure 5), indicating that these were using alternative deep sources of soil water to support the transpirational demand of the canopy. These data indicate that root pruning can redirect water uptake by trees to deeper soil layers, thereby avoiding stomatal closure and enabling them to continue to grow; however, if the canopy is not pruned, it will continue to compete with crops through shading and rainfall interception. Such effects are likely to vary with site, tree species, and planting density.

It is important to recognize that management for complementarity of water use by root pruning may detract from other potential advantages of tree-crop combinations, such as N fixation in root nodules by rhizobial bacteria and nutrient uptake by symbiotic mycorrhizal fungi associated with roots and proteoid roots, as these functions are more closely associated with surface than with deep roots.

Importance of Hydraulic Lift

Hydraulic lift is defined as the passive movement of water through the roots of trees from deeper and wetter soil layers to shallower and drier horizons along a gradient of soil water potential (Richards and Caldwell, 1987). This not only occurs nocturnally when transpiration is low, but may also occur during the day along water potential gradients induced by variation in soil salinity. This process redistributes water to topsoil, where it can be reabsorbed during subsequent periods of rapid transpiration. Hydraulic lift may be an important mechanism for avoiding drought stress by increasing daytime water supplies. This allows the stomata to remain open, enhancing assimilate production and growth in water-limited environments (Kizito *et al.*, 2012). Hydraulic lift has been demonstrated for more than 50 species from a variety of climates. Reverse hydraulic lift may also occur when downward movement of water between surface and deeper soil horizons occurs through roots (Jackson *et al.*, 2000). This process allows

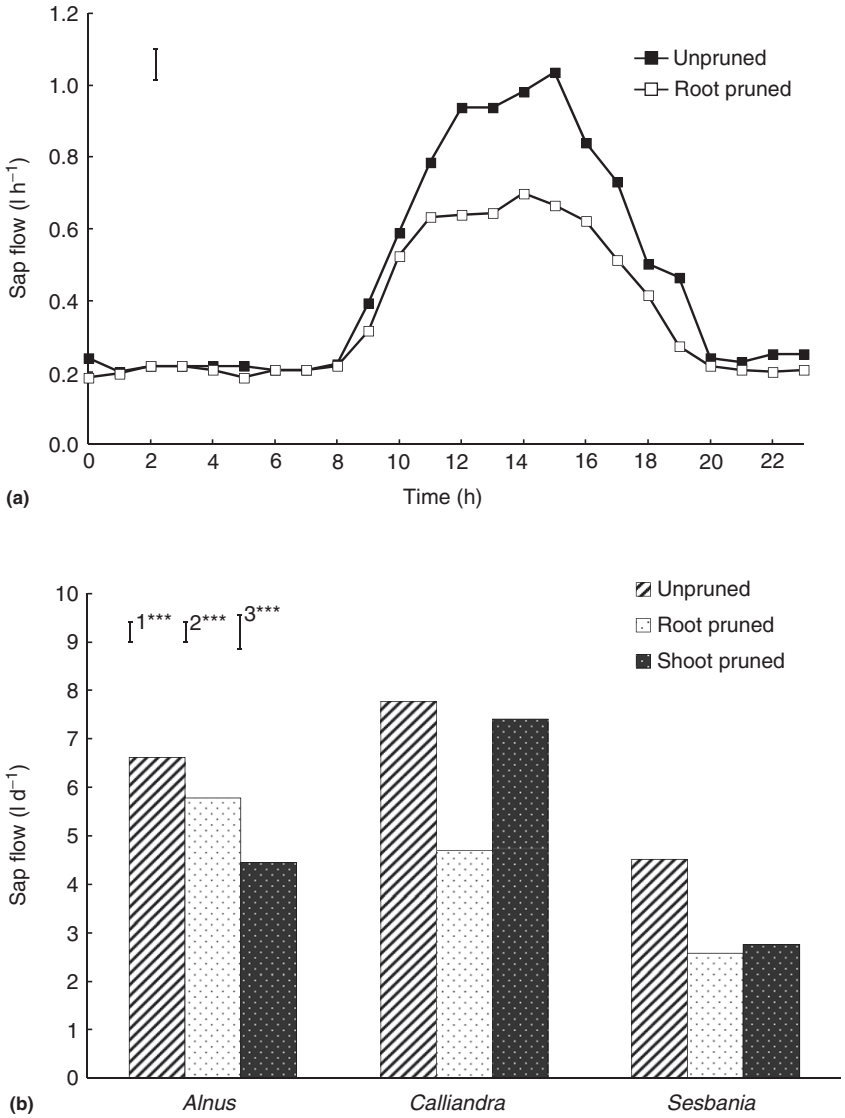

Figure 3 (a) Diurnal time courses of sap flow in unpruned and root-pruned *Grevillea robusta* trees shortly after root pruning was completed; vertical bar shows standard error of the difference (SED) (Anyango, 2005) and (b) influence of tree species and pruning treatment on mean daily sap flow rates for *A. acuminata*, *C. calothyrsus*, and *S. sesban*; vertical bars 1, 2, and 3 show SED values for species, pruning treatment, and tree-pruning treatment interaction. ***Denotes significance at $p < .001$ (Siriri, 2013).

a more rapid rehydration of deeper horizons when the topsoil is rewetted by rainfall than could be achieved by normal gravitational percolation.

In Africa, hydraulic lift amounted to 20% and 17.5% of the total volume transpired by *Vitellaria paradoxa* and *Parkia biglobosa*, respectively, in a semiarid Sahelian Parkland environment (Bayala *et al.*, 2008). In Australia, measurements for *Eucalyptus kochii* have shown that water redistributed by hydraulic lift contributes up to 27% of daily transpiration (Brooksbank *et al.*, 2011a); planting deep rooting trees that are able to exploit groundwater via hydraulic lift increased water use and biomass production by up to sixfold and tenfold, respectively, because roots were able to reach the relatively shallow water table (Brooksbank *et al.*, 2011a, 2011b, 2011c). The dimorphic root system of *F. albida* has both vertical and lateral roots, which allow it to tap groundwater to substantial depths, while still exploiting the surface horizons where nutrient supplies are greatest, suggesting the existence of hydraulic lift (Roupsard *et al.*, 1999). In Tanzania, Ludwig *et al.* (2003) observed that hydraulic lift only occurred during unusually wet years and was largely absent in *Acacia tortilis* during severe drought.

Thus, hydraulic lift may have a critical role in delaying soil drying and protecting fine roots in the topsoil from loss of hydraulic conductivity (Caldwell *et al.*, 1998). However, in the savannas of East Africa, the potentially beneficial effect of redistributing large quantities of water by acacia trees was offset by competition in the upper soil horizons (Ludwig *et al.*, 2004). Thus, the advantage of hydraulic lift depends on soil moisture content and other factors, such as soil depth, which are known to shape inter- and intraspecific interactions between plants.

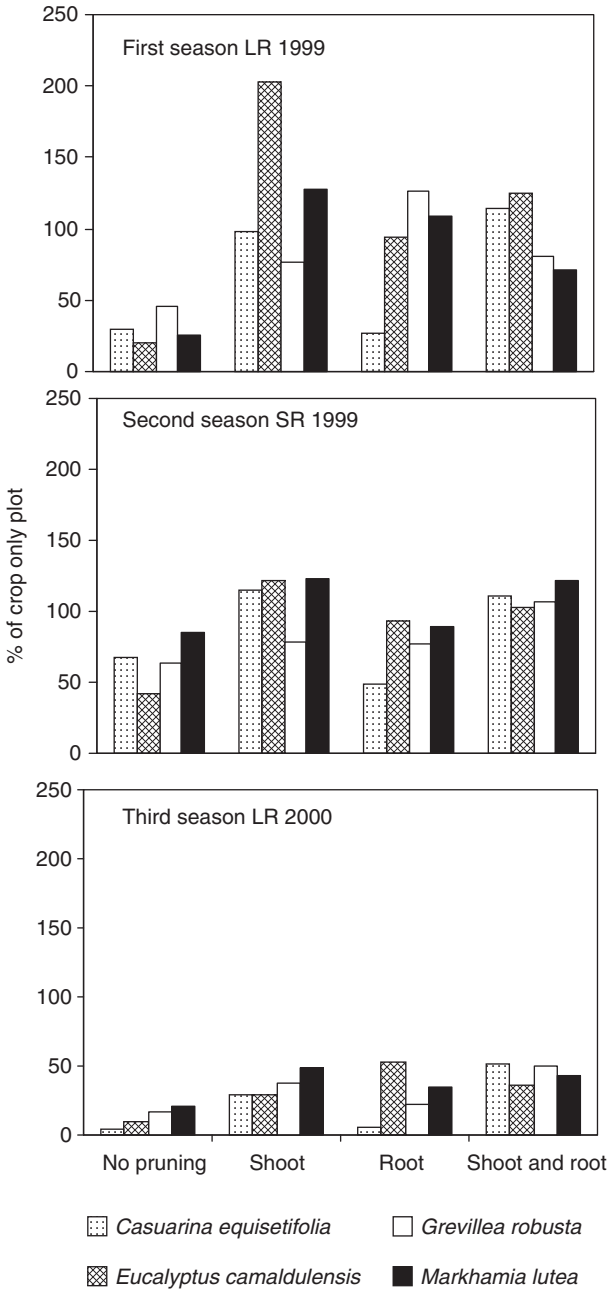

Figure 4 Effects of shoot, root, or shoot plus root pruning on maize yield relative to sole maize crops for four tree species. Data are for the first three cropping seasons after pruning at Siaya, Western Kenya. LR and SR represent long and short rains (Tefera, 2003). (Eds.), Below-Ground Interactions in Tropical Agroecosystems: Concepts and Models with Multiple Plant Components. Wallingford, UK: CABI Publishing, pp. 309–328.

Modeling the Impacts of Agroforestry

An overall assessment of whether AF systems use rainfall more effectively than a combination of woodlots and open fields can only be made when all components of the water balance are understood and compared. Furthermore, as it is not possible to make direct measurements of all possible tree and crop combinations, it is necessary to combine direct measurements with modeling. For example, analysis of water use in a *G. robusta*–maize AF system in semiarid Kenya has shown that approximately 59% of rainfall was lost by soil evaporation in the absence of a tree canopy, compared with approximately 44% under a tree canopy. This represents a substantial saving of approximately 117 mm year^{-1}, which was directly related to canopy cover, clearly demonstrating the potential improvement in water use that can be achieved by increasing ground cover in rain-fed agriculture (Wallace *et al.*, 1999).

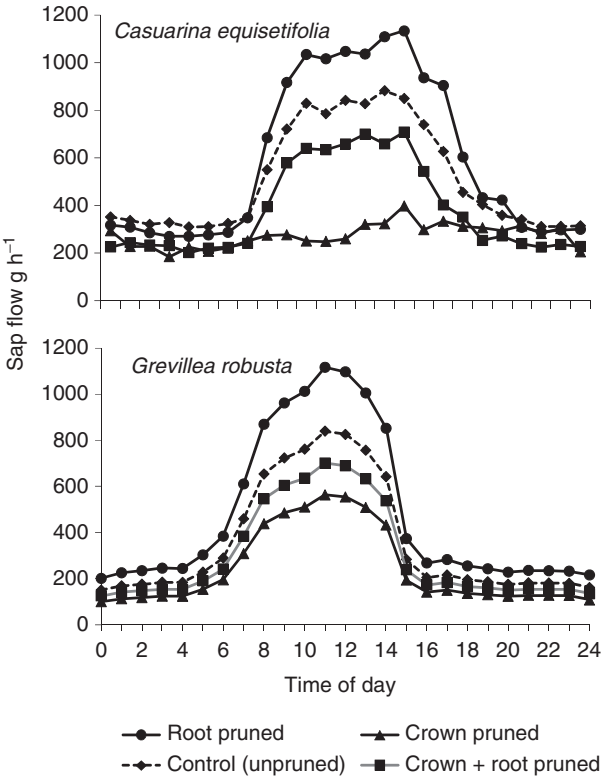

Figure 5 Effect of pruning treatment on mean daily time courses of sap flow for *Casuarina equisetifolia* and *Grevillea robusta* trees 2 years after tree pruning (Tefera, 2003).

The water, nutrient and light capture (WaNuLCAS) model developed by van Noordwijk and Luisana (2000) provides a convenient means of illustrating the impact of trees on water use at the landscape level when combined with sap flow measurements for individual trees. The impact of evergreen and deciduous trees in the drylands of East Africa was modeled using WaNulCAS (Muthuri *et al.*, 2005) to evaluate the impact of tree leafing phenology on crop performance and soil water balance. The hypothesis that deciduous trees, which shed their leaves for much of the dry season, would reduce water requirements was tested using three species, *G. robusta* (evergreen), *A. acuminata* (semideciduous), and *Paulownia fortunei* (deciduous). The leafing phenology of each species was categorized using three criteria: leaf flush, leaf fall, and leaf cover (Figure 1). The model output suggested that (1) leafing phenology is one of the most important tree attributes with respect to water consumption; (2) lower water use by

deciduous species should increase stream flow compared with evergreens; and (3) deciduous tree species are suitable for the semiarid areas examined and provide viable alternatives to evergreen species such as *Grevillea*.

Conclusions

This article shows that trees may have both beneficial and detrimental hydrological impacts at farm and watershed levels. Temporal complementarity in the use of rainfall occurs if residual water is available after the crop is harvested or rainfall occurs when there is no scope for cropping. The most remarkable example of temporal complementarity in water use is the unusual phenology of the Sahelian tree, *F. albida*, which is leafy during the dry season and sheds its leaves during the rainy season. Improved soil water and nutrient status has been reported under mature tree canopies in the savanna areas of Africa, Central America, and North America. In theory, trees can enhance soil water content beneath their canopies if the water saved through decreases in soil evaporation caused by shade and reduced runoff exceeds the quantity of water removed by their root systems. Hydraulic lift by tree roots may also redistribute water from moist zones deep in the soil profile to the surface horizons. However, spatial complementarity in water use is rare as tree and crop roots often exploit the same surface soil horizons and rainfall seldom recharges horizons below the crop rooting zone, although there is clear evidence of spatial complementarity when groundwater is accessible to tree roots.

Containing competition for water, nutrients, and light between trees and crops in AF systems remains a major challenge in the semiarid tropics, especially in the search for an acceptable substitute for eucalyptus. In Southern Australia, the greatest challenge is to find tree species that provide valuable products and improve the poor drainage, which is responsible for inducing salinity in millions of hectares of profitable farm land, with minimal loss of crop yield.

Finally, there is an urgent need to consider the impact of climate change on water use by trees, which has received surprisingly little attention. Previous studies of watershed functions of forests and AF systems have focused on reward schemes to upstream communities for providing environmental services to downstream users, whereas Clean Development Mechanism schemes in Africa have focused chiefly on global benefit. Rewards may well be an efficient and fair way of investing international funds in climate-change adaptation, which will have profound hydrological impacts on AF at both local and global scales (van Noordwijk *et al.*, 2011).

Agroforestry: Participatory Domestication of Trees

RRB Leakey, James Cook University, Queensland, Australia

© 2014 Elsevier Inc. All rights reserved.

Glossary

Apical dominance The process which regulates branching in plants.
***Circa situ* conservation** It is conservation through wise use.
Cultivar A cultivated variety.
Ideotype The combination of a number of genetic traits that confer superiority in quality or yield.
Participatory rural appraisal Identification of the needs of local communities through dialog.

Introduction

The domestication of agroforestry trees is a technique for the intensification of agroforestry as a low-input farming system delivering multifunctional agriculture for the relief of poverty, malnutrition, hunger, and environmental degradation in tropical and subtropical countries (Leakey, 2010, 2012a).

In the past, tree products were gathered from natural forests and woodlands to meet the everyday needs of people living a subsistence lifestyle. With the advent of the Industrial Revolution and, more recently, the intensive modern farming systems of the Green Revolution, the resource of these trees has declined. This has been due to increased population pressures for agricultural land and the escalation of deforestation. To rebuild and improve this useful resource, the concept of tree domestication for agroforestry was proposed in 1992 (Leakey and Newton, 1994) and subsequently implemented by the World Agroforestry Centre (International Centre for Research in Agroforestry (ICRAF)) as a global initiative from 1994 (Simons, 1996). Great progress has been made in the first two decades of this initiative (Leakey *et al.*, 2005, 2012; Tchoundjeu *et al.*, 2006, 2008), which have encouraged local entrepreneurship in the processing and marketing of agroforestry tree products (AFTPs). This has had beneficial impacts on farmers' livelihoods (Tchoundjeu *et al.*, 2010).

Strategy

Domestication through cultivar development relies on three processes: selection, testing, and breeding. Selection identifies certain genotypes for cultivar development, testing exposes the new cultivars to appropriate environments, and breeding creates new genetic variability.

As in animals, plant domestication is a continuous process that, in crops like wheat, rice, maize, oranges, and apples, started thousands of years ago and continues today. In trees, two basic approaches are used to effect genetic improvement: the seed-based breeding approach typical of forestry and the clonal approach typical of horticulture, but the domestication strategies are not dissimilar. In agroforestry, Leakey and Akinnifesi (2008) have suggested a strategy based on the establishment of three interlinked tree populations (**Figure 1**):

- Gene resource population.
- Selection population.
- Production population.

The gene resource population is basically the wild population from which new selections can be derived. The selection population is the collection of selected provenances, progenies, or individual trees which are being tested and used to develop clonal cultivars or integrated within breeding programs to create the next generation of breeding stock. A wide range of genotypes may be kept in this population as long as each one has at least one characteristic of possible future interest. The production population consists of the highly selected clones, progenies, or provenances which are currently being planted by farmers.

In their strategy paper, Leakey and Akinnifesi (2008) specifically highlighted the development of a clonal approach to the domestication of high value trees, particularly the traditionally important indigenous fruits and nuts. However, the key element of the tree population strategy is equally applicable to less valuable tree species grown for their environmental services and propagated by seed. It is important to remember that the practice of domesticating a species is cyclical and thus continuous. For this reason, commercial plantings have to be made with whatever material is best at a given time, knowing that they will be superseded later.

The strategy being implemented by ICRAF and others to domesticate high-value indigenous trees for agroforestry, such as those producing marketable fruits and nuts, is based on participatory processes involving local communities. A participatory tree domestication strategy involves the consultation with and participation of farmers to (1) determine their priority species for domestication (Franzel *et al.*, 1996, 2008) (2) make an inventory of the natural resource, (3) implement a program of genetic selection and mass propagation aimed at the sustainable production of AFTPs for food, tree fodder, medicinals and nutriceuticals, timber, wood and fibers, etc., and (4) sell and trade the products in local traditional and new emerging markets further afield. Such strategies also recognize the importance of the wise use and conservation of genetic resources; the reduction of deforestation and restoration of degraded land. Participatory approaches have numerous advantages (Leakey *et al.*, 2003) such as building on tradition and culture and promoting rapid adoption by growers to enhance livelihoods and environmental benefits (Simons and Leakey, 2004). This participatory approach to domestication, therefore, differs from the more common scientific approach that has typically been implemented to develop most food crops. Therefore these approaches can be thought of as the 'farm' and the 'research station' pathways to domestication. In

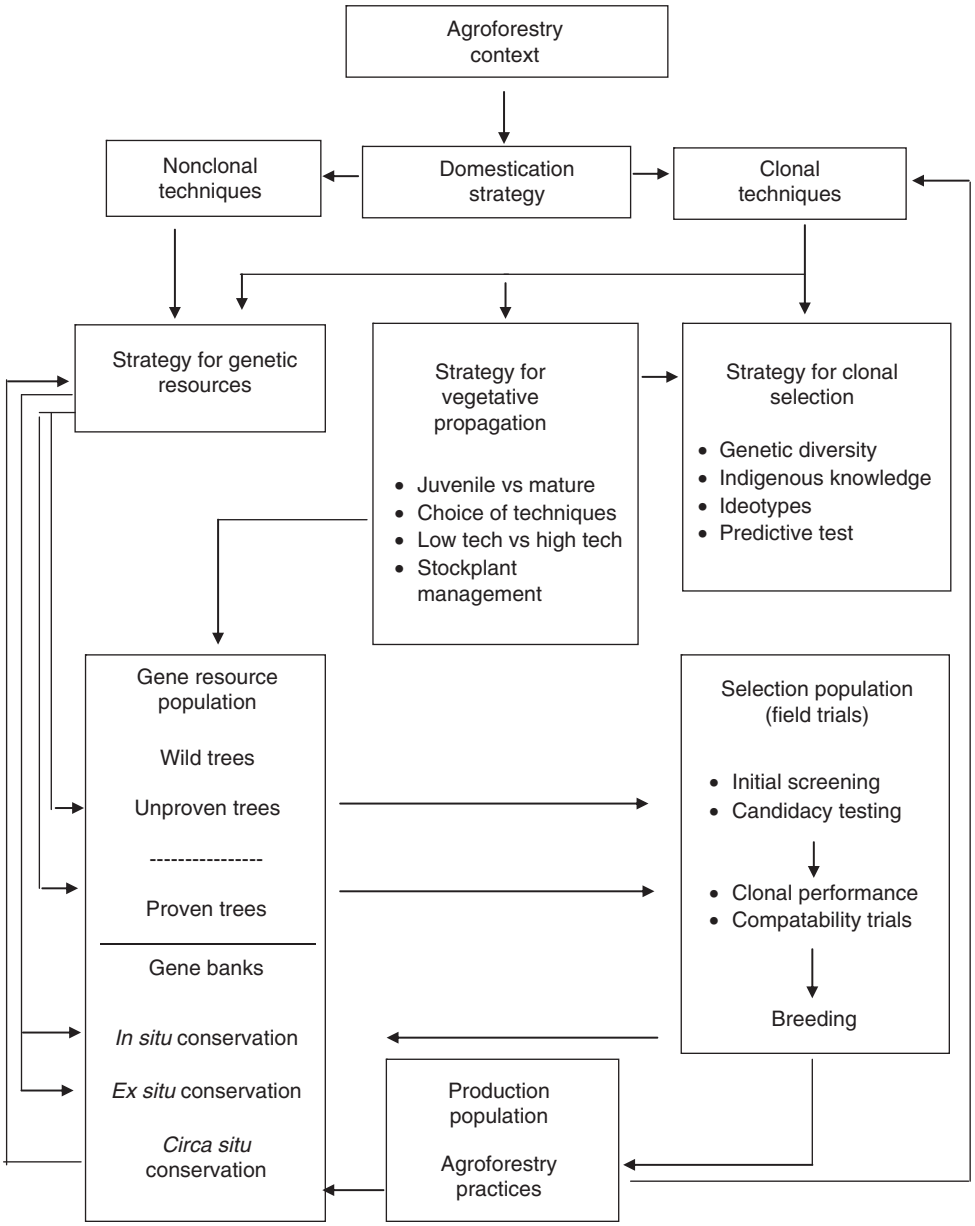

Figure 1 The agroforestry tree Domestication Strategy and the relationships between a Genetic Resources Strategy and the Strategies for Vegetative Propagation and Clonal Selection. Reproduced from Leakey, R.R.B., Akinnifesi, F.K., 2008. Towards a domestication strategy for indigenous fruit trees in the tropics. In: Akinnifesi, F.K., Leakey, R.R.B., Ajayi, O.C., *et al.* (Eds.), Indigenous Fruit Trees in the Tropics: Domestication, Utilization and Commercialization. Wallingford, UK: CAB International, pp. 28–49.

agroforestry, these two pathways have been integrated (Figure 2) in a way that ensures that the participating farming communities can benefit from the close involvement of researchers as mentors both to the communities and the Nongovernmental Organizations (NGOs) implementing the domestication program.

Biological Components of the Strategy

Propagation of superior trees

The choice of mass propagation by the clonal approach has a number of advantages stemming from the use of vegetative propagation to capture and fix desirable traits, or combinations of traits, found in individual trees (Leakey and Simons, 2000). The main advantage arises from the fact that by taking a cutting, or grafting a scion onto a rootstock, the new plant which is formed has an exact copy of the genetic code of the plant from which the tissue was taken and is, therefore, genetically identical to the stockplant or 'mother' plant . The clone so formed can be mass produced by further vegetative propagation.

The capture of the first asexual propagule from proven and mature field trees that have already expressed their genetic traits is typically done in the field by air-layering/marcotting shoots on the mother tree or by collecting scions or buds from it for grafting or budding onto seedlings in the nursery.

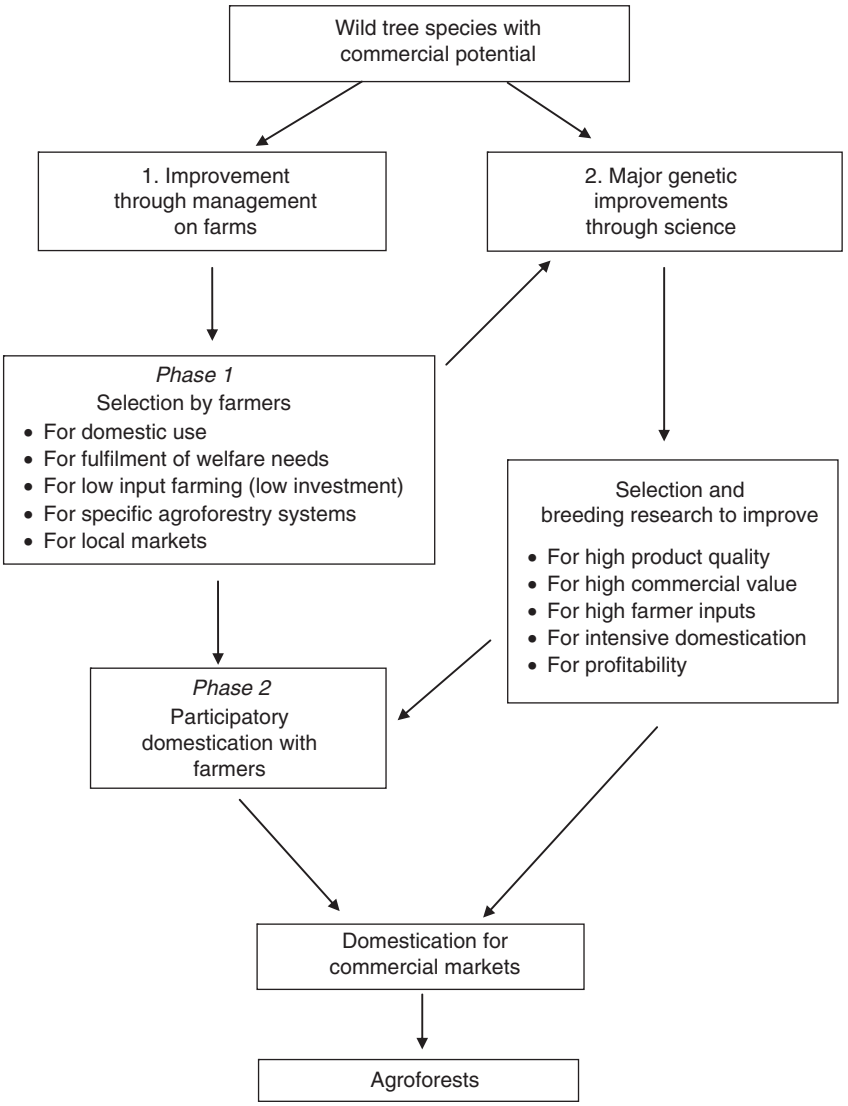

Figure 2 Tree domestication pathways. Reproduced from Leakey, R.R.B., Akinnifesi, F.K., 2008. Towards a domestication strategy for indigenous fruit trees in the tropics. In: Akinnifesi, F.K., Leakey, R.R.B., Ajayi, O.C., *et al.* (Eds.), Indigenous Fruit Trees in the Tropics: Domestication, Utilization and Commercialization. Wallingford, UK: CAB International, pp. 28–49.

Alternatively, the tree can be felled and the stump left to coppice to provide juvenile material for propagation by stem cuttings. The latter is preferable for clonal timber production from trees with a well-formed juvenile stem, whereas the former is more suitable for trees producing fruits on mature branches (Leakey and Akinnifesi, 2008). The advantage of propagating fruit trees from mature branches is that they already have the reproductive capacity to form flowers and fruits. This means that they are productive within a few years, thus reducing the time taken to produce economic returns. Plants propagated from mature tissues will also have a lower physical stature, making the harvesting of fruits easier (**Figure 3**).

Once the clone has been formed by one or other of the above techniques, the best strategy is to mass produce the clone, or cultivar, by rooting cuttings in the nursery. For this process, inexpensive and simple nonmist propagators have been developed (Leakey *et al.*, 1990). This simple, low-technology strategy allows the process to be implemented in remote areas without electricity or running water. These propagators are also extremely effective and meet the needs of most developing country tree domestication projects in both the moist and dry tropics.

The above strategy of capturing the genetic superiority of mature trees in the field may not always be possible or acceptable, making it necessary to develop clones from seedling plants in the nursery. Basically, this adds an additional genetic selection step to the overall domestication program, which can take many years to complete. Nevertheless, there are three reasons why the use of seedlings may be preferable (Leakey and Simons, 2000):

1. The population of mature trees can be dysgenic (genetically depleted) because the elite specimens have been removed by loggers or farmers. In this case, the seedling progeny

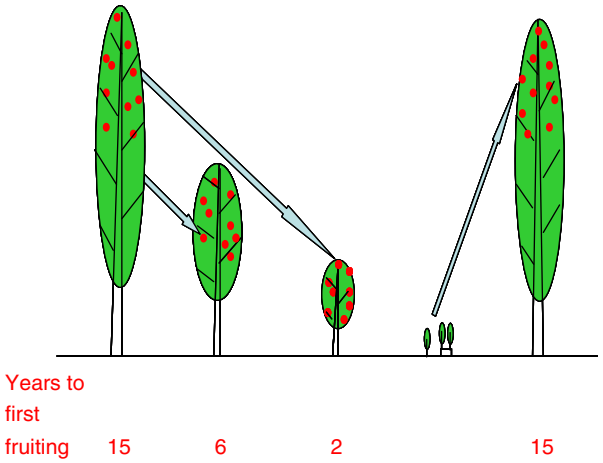

Figure 3 Designing trees of different sizes for different uses by selecting the source of the propagation material *vis-à-vis* the state of maturation in the tree. Reproduced from Leakey, R.R.B., 2012b. Living with the Trees of Life – Towards the Transformation of tropical Agriculture. Wallingford, UK: CABI, 200 pp.

derived from such populations will probably have a better array of genetic variation during reproduction due to the remixing of genes during the segregation phase of meiosis.

2. The felling of large numbers of the most desirable mature trees for the purpose of generating cultivars may not be acceptable to the owners. In addition, felling the mature trees may not be environmentally acceptable.
3. The use of seedlings allows the screening of far larger populations, with much more diverse origins, thus maintaining genetic diversity among the cultivars.

Through the improvement of tree yield and product quality, tree domestication becomes a strategy for the intensification of agroforestry (Leakey, 2012a), something which is further enhanced when many of the different trees within the farming systems are domesticated in parallel.

Genetic resource issues

One of the important requirements of an appropriate strategy is to conserve a substantial proportion of the genetic variability for future use in selection programs and, subsequently, through breeding to broaden the genetic base of the cultivars in the Production Population. This also serves as a risk aversion strategy should it be necessary in the future to breed for resistance to pests and diseases. There are three actions which each contribute to genetic conservation:

- Establishing a Gene Bank (*ex situ* conservation).
- Wise utilization of the genetic resource in cultivation (*circa situ* conservation).
- Protecting some wild populations (*in situ* conservation).

Ex situ gene banks containing randomly sampled populations from across the natural range of the species should be replicated within a site and across a number of sites. This replication is both for security and to ensure that the sites embrace any climatic or edaphic variation within the region. They should also be located in areas offering long-term protection from external threats, for example, deforestation and wild fires.

Regarding *circa situ* conservation and the wise use of genetic resources, it is important to recognize that there is a trade-off between accuracy of genetic value estimation and intensity of selection (i.e., greater accuracy generally comes at the expense of reduced numbers of families, individuals per family, or clones). In long-lived tree crops, there is also the problem that many of the traits on which selection is based are not visible until the trees are nearing their productive age at the end of a long period of growth. Consequently, in timber trees, for example, much selection is done on early rates of growth and assumptions that this will relate to yield. In the case of the West African tree *Triplochiton scleroxylon*, a Predictive Test was developed on the basis of apical dominance (the process controlling the formation of branches) in very young plants in the nursery. This was to take advantage of a strong relationship between this physiological process and branching frequency in the nursery and then between branching frequency in the field and stem volume or timber yield (Leakey and Ladipo, 1987). A quick and early test like this allows much larger populations to be screened than would be either practical or economically justifiable through long-term field trials.

The trade-off between the intensity of selection and number of plants also affects the diversity of the genetic base – the gene resource population. This diversity should be rigorously enforced as one of the objectives of a domestication program. This, therefore, involves a good sampling protocol both of the natural population as well as for any existing provenances and progenies from a breeding program. In this respect, it is important to remember that it is not uncommon for there to be a few elite trees in provenances and progenies which may, however, on average, be poor. This is especially important if a clonal domestication program is being developed, as these elite individuals from poor populations may be genetically unique.

As the selection process intensifies with time, new traits will be introduced into the domestication program (e.g., seasonality of production, early fruiting, disease and/or pest resistance, drought tolerance, etc.). After the initial phases of clonal selection, the opportunity will arise for controlled pollinations between proven elite clones as has been done in *Ziziphus mauritiana* (Kalinganire *et al.*, 2012) in the Sahel and *Dacryodes edulis* in Cameroon (Makueti *et al.*, 2012). In this way, it should be possible to take advantage of specific-combining ability in unrelated superior clones and to produce progeny with heterosis in desirable traits that exceed what is found in the wild populations. The vegetative propagation of these new genotypes can become a second clonal generation.

Environmental Components of the Strategy

Different agroforestry practices typically involve a range of different species producing environmental/ecological services such as soil fertility enhancement, erosion control, or different products ranging from low-value fuel wood to high-value marketable products for food, cosmetic, and pharmaceutical industries. Different approaches to domestication will probably be followed for these different species. Likewise, these

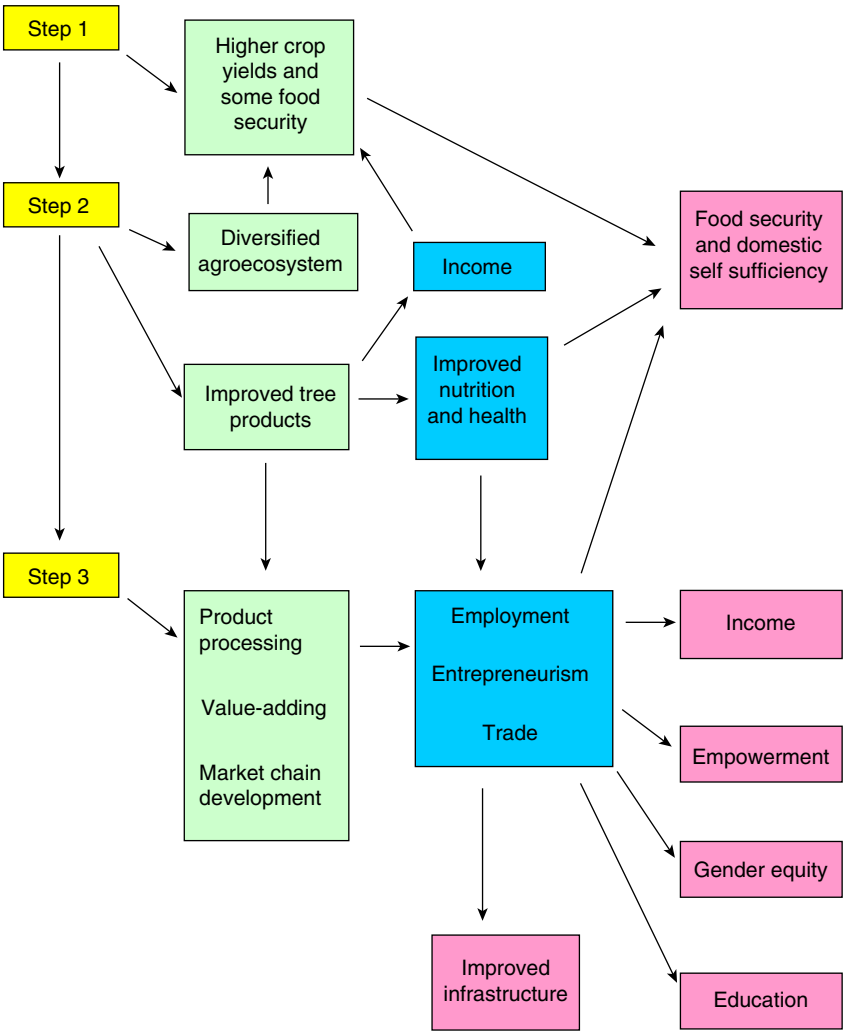

Figure 4 The delivery of multifunctional agriculture by three agroforestry steps. – Step 1. Land rehabilitation with leguminous trees and shrubs, Step 2. Domestication with indigenous trees producing marketable products, and Step 3. Marketing, processing, and value-adding indigenous tree products (see **Table 1**). Modified from Asaah, E.K., Tchoundjeu, Z., Leakey, R.R.B., *et al.*, 2011. Trees, agroforestry and multifunctional agriculture in Cameroon. International Journal of Agricultural Sustainability 9, 110–119.

different species will probably fill different spatial and temporal niches in the landscape and be planted in different configurations and densities within farming systems. This is all part of the diversification of the agroecosystem which is an important component of enhancing agroecosystem functions for the rehabilitation of degraded farmland (Leakey, 1999a, 2012b).

The domestication of indigenous trees producing high-value products, such as traditional foods and medicines, is one component of a novel strategy for the intensification (Leakey, 2012a) and diversification (Leakey, 2010) of smallholder farming systems in the tropics and subtropics through agroforestry. In environmental terms, the diversification with long-lived perennial plants is important because it is the way to rebuild the ecological functions of agroecosystems and landscapes. Soil and land rehabilitation is crucial if agriculture is to use land already cleared of forest rather than abandoning it and cutting down more forest (Leakey, 2012b).

Tree domestication and the commercialization of tree products also create incentives for farmers to plant agroforestry trees as they generate income and promote business, trade, and employment opportunities. When added to agroecosystem rehabilitation, tree domestication can be seen as step two in a generic model of how agroforestry can deliver environmentally desirable multifunctional agriculture (Leakey, 2010; Leakey, 2013; **Figure 4**) – a model with high adaptability to different climatic and edaphic situations (Leakey, 2012b).

Social Components of the Strategy

Many of the biological components described in the Section Biological Components of the Strategy are not specific to Participatory Domestication and would apply to more centralized and top-down programs led by research scientists. In

contrast, the social components are central to the philosophy of Participatory Domestication.

The prime objective of the participatory approach is to involve the target communities in all aspects of the planning and implementation of the program so that they fully understand it and can 'buy-in' and have ownership of the program. In addition, the purpose of this strategy is also to ensure that all engaged members of the community, whether male or female, are empowered by the program and are the beneficiaries of the outputs of their own initiatives and labor. This should enhance the livelihoods of the community members in general and promote social equity.

In the longest-running example of participatory domestication in agroforestry trees, the researchers have fed their outputs to NGO partners through training-of-trainers courses and by acting as mentors to the NGO-managed farmer-training schools (or Rural Resource Centers) established in pilot villages (Tchoundjeu *et al.*, 2002, 2006, 2010; Asaah *et al.*, 2011). As it will be seen in the Section Techniques, the farmers in this partnership have contributed their knowledge about the use and importance of local species, the range of variation in different traits of relevance to genetic selection, and their traditional knowledge (TK) about the role of these species in local culture and tradition. They have also contributed their time and labor. Furthermore, and crucially, they have also made available some of their trees for research and training in domestication techniques.

In implementing this strategy, it is of great importance to recognize the legal and socially important communal rights of local people to their TK and local germplasm (Lombard and Leakey, 2010) and to ensure that they benefit from their use and are rewarded for sharing them for the wider good. Because of the sensitivity arising from past commercial exploitation of these rights by individuals, companies, academics, international agencies, and government, it is very clear that the partners in domestication programs have to earn the trust of local communities before TK and germplasm is made freely available. Ideally, to ensure that benefits flow back to the farmers and communities, the recipients of TK and germplasm should enter into formal 'Access and Benefit Sharing' agreements (ICRAF, 2012) in which the rights of the holders of knowledge and genetic resources will be legally recognized.

Commercial Components of the Strategy

With poverty alleviation as one of the objectives of the domestication of agroforestry trees, it is clear that incentives for and approaches to income generation are important in the overall strategy. Consequently, improving and expanding the markets for agroforestry trees and their products are central to the strategy.

The first opportunity is the creation of demand for agroforestry trees, whether for environmental and ecological services or for AFTPs. This, certainly, involves the dissemination of the importance of agroforestry for soil fertility replenishment, watershed protection, reduction of erosion, demarcation of boundaries, as well as for the production of wood for fuel and other uses, timber, extractives, medicines, fodder, food, and numerous nonfood products (Leakey, 2012b). The experience of the past 10–15 years indicates that the first income stream from agroforestry projects is derived from the sales of plants from village nurseries to neighboring communities, especially the sale of seedlings of nitrogen-fixing or the so-called 'fertilizer' trees (Asaah *et al.*, 2011; Leakey and Asaah, 2013). This is because the loss of soil fertility due to frequent cropping without access to artificial fertilizers is recognized as one of the main constraints to agricultural production. In addition, the benefit flow from these trees is obtained relatively quickly (1–3 years). However, it generally takes longer to obtain returns from the production of AFTPs.

The strategy for increased income generation from AFTPs is, in the first instance, to build local markets and trade. This is particularly important in the case of traditional foods and medicines as local people are familiar with the use of these products and the demand typically exceeds supply. In the longer term, however, some of these products may have regional and even international markets, firstly with expatriates from tropical countries living in Europe and America, and then as products become more widely known or better processed with global customers.

A secondary reason for focusing on local and regional rather than international markets is that if the demand expands too fast there is a risk that large-scale entrepreneurs may enter the marketplace and outcompete local business people (Leakey and Izac, 1996) thus, undermining the use of tree domestication as a development strategy. Having said that there are a few interesting and potentially very important initiatives in which multinational companies are becoming engaged with local communities in tropical countries in Public–Private Partnerships (Leakey, 2012b). These are generally operating in a way that is contrary to the trend of globalization in which all the economic benefits flow to industrial countries rather than at least some remaining in the tropical country.

Some tree products, notably fruits, are produced seasonally and have a very short shelf life. To overcome this constraint to year-round marketing, it is necessary to investigate opportunities for processing and value adding. This can take many forms such as drying and airtight packaging; preservation in oil, brine, or syrup; and freezing, etc. Generally, this involves the need for a level of scale outside the capacity of a smallholder farmer, although 'cottage' industries can be a possibility. If this approach to extending the marketing season has to involve industrial companies, then new issues arise. One of these is to involve the companies in the domestication process so that traits which are important in the processed product are included in the genetic selection program (Leakey, 1999b). Later, issues of trading agreements that also result from the involvement of processing companies in marketing will be considered.

An alternative approach to processing can be to seek the generally rare plants that flower and fruit outside the normal seasonal pattern and then to develop these as cultivars. Although this can be quite simple to achieve, these out-of-season plants may not have quality or yield traits that are as good as those fruiting within the normal season. In this case, developing cultivars which expand the productive season may need to also involve a breeding program.

As the commercialization process involves more players and becomes more complex, the risks that the producers will

be exploited and inadequately rewarded for their products and innovations increase. Entering into any market will expose suppliers to competition. Commentators have suggested that this will undoubtedly jeopardize the rights of farmers or communities in the supply chain. To shut out casual and opportunistic competitors, it is obviously important to do as much as possible to ensure that the supply chains leading up to the manufacture of the products are efficient, competitive, and as well protected as possible. Innovative approaches to ensuring that farmers and local communities are rewarded for their innovations have been developed by PhytoTrade Africa (Lombard and Leakey, 2010). It has been engaged in addressing the sustainable commercialization of natural products produced by indigenous plants, especially the trees of the Miombo woodlands. PhytoTrade Africa believes that the risks of exploitation can be minimized if the primary producers are able to secure long-term access to the markets developed for their products. Thus, they have worked to ensure that markets can be secured so that supply chains can emerge so that as wild harvesting leads to domesticated or farmed sources, the initial producers are protected as much as possible. The approach involves working with indigenous communities and helping them to secure long-term access to local and even international markets in ways which reward them and protect their intellectual property rights. Experience to date indicates that these approaches can result in critically important supplementary income of otherwise poor and marginalized farmers and producers. This, in turn, significantly improves their livelihoods.

This partnership approach between producers and the local-to-global cosmetic, food, beverage, herbal medicine, and pharmaceutical industries is based on four areas of intervention aimed at the propoor commercialization of the traditionally important products:

- Product development.
- Market development.
- Supply chain development.
- Institutional development.

Such partnerships are developed by carefully constructing commercial agreements with leaders in the relevant sector. Critically, this involves the establishment of strong and viable trade associations that are forward thinking and market oriented. Through these partnerships, it is possible to ensure long-term relationships and supply agreements which ensure that the farmers and local community producers remain in the value chain. The achievement of this can, under certain circumstances, also create a barrier to entry for plantation developers who might wish to outcompete small-scale producers and farmers.

One important consideration in developing these partnerships is the selection of appropriate species. It is critical that the abundance of the resource, and the ownership over the resource by the target producers, is sufficient to ensure sustainable and reliable supply of the products. To date, small-scale producers have depended on wild harvesting to supply the local markets. Although this provides a supply-related barrier to large scale trade that favors small-scale producers, it also imposes constraints to the market expansion that is needed to raise these producers out of poverty. For example, wild products are highly variable in quality, often with unreliable levels of production. However, the focus on naturally occurring wild resources is now changing with the recent emergence of highly compatible propoor participatory domestication technologies for indigenous fruit and nut trees. This offers great opportunities to improve product quality through tree selection and cultivar development. Creating these new crops should also greatly increase the supply of very marketable produce. Thus, by realizing the importance of 'commercialization for domestication' and 'domestication for commercialization,' there is considerable opportunity for agroforestry to alleviate poverty, malnutrition, and hunger in marginalized agricultural communities of developing countries. Thus, the symbiotic relationship between domestication and commercialization is a very important aspect of the strategy needed to ensure real impact on the big socioeconomic issues affecting the world. The overall outcome of such developments arising from improved agricultural production and enhanced livelihoods should, therefore, be improved access to clean water, better diets, healthcare, education, etc. Just as it is seen above regarding adaptability to different environmental situations, this model case has great adaptability to different socioeconomic situations (Leakey, 2012b).

Thus, in conclusion, when the social and commercial components of the strategy that have been developed for participatory domestication strategy are added to the agroecosystem benefits from the adoption of agroforestry for land rehabilitation, the emergence of a three-step generic model for the delivery of a socially and economically desirable multifunctional agriculture by agroforestry can be seen (**Figure 4**, **Table 1**).

Before moving on, however, it is important to recognize that the trade in some new products will require regulatory approval for European Union (EU) and American markets. It is, however, possible to tie the approval of these products to the target producers, as has been achieved by PhytoTrade Africa's successful application to have Baobab fruit approved as a novel food ingredient in the EU under Regulation (EC) 258/97 and by Unilever Deutschland GmbH for *Allanblackia* seed oil (European Food Security Authority No EFSA-Q-2007-059.

Techniques

Biological Components of the Techniques

Genetic selection

The domestication process is basically about the cultivation of plants with superior genetic traits. In trees, two techniques can be used to assist in the identification of superior mature trees (sometimes called 'elite' or 'plus trees') producing timber and wood, indigenous fruits and nuts, or otherwise useful everyday domestic products. In forestry for timber and wood production, genetic improvement is typically done by selection of a population with inherent genetic quality (a provenance) and by making seed collections from that population. Alternatively, when more is known about the genetic quality of individuals within a population, seeds (a progeny) are typically collected from the best mother tree(s). The same

Table 1 The 3-step model for multifunctional agriculture

- Step 1: Adopt agroforestry technologies such as two year 'Improved fallows' or 'Relay cropping' with nitrogen-fixing shrubs that improve maize yields from approximately 1 ton ha^{-1} per hectare up to approximately 4–5 tons ha^{-1}. This allows the farmers to both improve food security and reduce the area of their holdings planted with maize and thus make space for other crops, perhaps cash crops which would generate income. An additional benefit arising from improved fallows with leguminous shrubs is the reduction of parasitic weeds like *Striga hermontica* and the reduced incidence of insects pests like the stem borers of maize.
- Step 2: Diversify the farming system by the inclusion of species producing marketable products or fodder for livestock. The adoption of participatory approaches to the domestication of traditionally important indigenous food plants is a good way to rapidly create new cash crops that generate income, improve nutritional security through diversified diets, enhance gender equity, provide diversified diets rich in micronutrients, empower communities toward self-sufficiency in products of day-to-day domestic importance, and maintain culture and traditions. The sale of these products would allow the purchase of fertilizers and thus, potentially, the increase of maize yields up to 10 tons ha^{-1}. Consequently, the area under maize could be reduced further to allow more cash cropping. The integration of fodder trees and livestock into a farm is one of the elements of diversification that could be part of this step.
- Step 3: Promote entrepreneurship and develop value-adding and processing technologies for the new tree crop products, thus increasing availability of the products throughout the year, expanding trade, and creating employment opportunities. All of these are outputs which should help to reduce the incidence of poverty and enhance gender equity.

(Ed.), Handbook on Agroforestry: Management Practices and Environmental Impact. Environmental Science, Engineering and Technology Series. New York, USA: Nova Science Publishers, pp. 461–471 and Leakey, R.R.B., 2013. Addressing the causes of land degradation, food/nutritional insecurity and poverty: A new approach to agricultural intensification in the tropics and sub-tropics. In: Hoffman, U. (Ed.), UNCTAD Trade and Environment Review 2012. Geneva, Switzerland: UNCTAD. Available at: www.unctad.org/Templates/Page.asp?intItemID=3723&lang=1 (accessed 16.09.12).

approach is used in agroforestry when cultivating trees for soil fertility enrichment or for wood products such as poles or wood fuel (i.e., environmental services or low-value products). However, in agroforestry, trees are also cultivated for high-value useful or marketable products like fruits, nuts, medicines, or other chemical ingredients. In this case, domestication is often done using vegetative propagation to develop cultivars or clones, and participatory approaches involving local communities are appropriate.

In the participatory domestication of trees producing indigenous foods two approaches to genetic selection can be adopted. The first is to seek the knowledge of local people about which trees produce the best products (see 'social components of the techniques' given below as to how to ensure that their traditional rights are recognized). The second, more scientific, technique involves the quantitative characterization of many traits of fruits, kernels, and leaves, which are associated with size, flavor, nutritional value, etc. This characterization also determines the extent of the tree-to-tree variation. This more scientific approach can be used to 'backstop' or enhance the indigenous knowledge approach by adding new knowledge about marketable or commercially important traits to enrich the indigenous knowledge. Over the past two decades, much scientific knowledge has been acquired to support the participatory domestication initiatives being implemented around the world (see review by Leakey *et al.*, 2012; Leakey, 2012b).

In the scientific approach to selection, modern laboratory techniques are being increasingly used to examine traits which are not visible to the naked eye. For example, to quantify genetic variation in the chemical and physical composition of marketable products such as polysaccharide food-thickening agents, nutritional content (protein, carbohydrate, oils, fiber, vitamins, minerals, etc.) by proximate analysis, medicinal factors like antiinflammatory properties, the composition of essential oils and fatty acids, the determination of wood density, strength, shrinkage, color, calorific value, and other important wood properties correlated with tree growth (Leakey *et al.*, 2012). In addition, molecular characterization

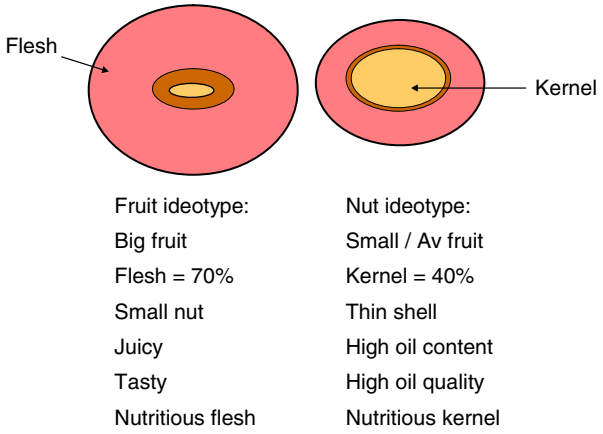

Figure 5 Some traits of different trees which can be combined to form the ideal tree for fresh fruit or kernel production – an Ideotype.

of the genetic code is being used to determine the structure of genetic variation in natural, managed, and cultivated tree stands and to devise appropriate management strategies that benefit users (Jamnadass *et al.*, 2009). This information is used to determine the proportion of a species' genetic variation that is available at a local geographical scale, whether or not cultivated stands are of local or introduced origin, and to ensure that domesticated populations have sufficient genetic diversity to avoid future problems from inbreeding (Pauku *et al.*, 2010).

The above scientific inputs to the understanding of genetic variation can then inform the process of farmer selection and help to provide guidance of how best to meet the needs of different market opportunities. To achieve this, the concept of 'ideotypes' developed for the breeding of cereals has been modified in order to assist tree selection (Leakey and Page, 2006). An ideotype is the ideal combination of traits for a cultivar to produce a product that meets the needs of a particular market (**Figure 5**). So, for example, an ideotype for a fresh fruit would have a lot of flesh (and small seeds/nuts/kernels), be sweet, juicy, tasty, nutritious, and look attractive.

However, a nut ideotype would have a large kernel(s) (and probably little flesh), have a thin shell so that it is easily cracked, be rich in edible oil with an appropriate fatty acid profile, or have other characteristics meeting the needs of the cosmetic or pharmaceutical industries. In both instances, these quality traits are ideally associated with a high yield of fruits or nuts, so that the cultivar can be said to have a high 'harvest index' – a large amount of 'ideal' harvestable product.

An obvious trait for inclusion in the selection of all cultivars for food products is their nutritional quality. Although it is known that the tree-to-tree variation is substantial in these traits, and indeed in antinutritional factors such as phenolic content, there is a lack of knowledge on the extent of this variation in most species. Instead, most researchers have published the average values per species. This allows some comparison between species but is not useful when seeking to select cultivars from within a species. Likewise, there is very little information about tree-to-tree variation in taste, but again it is known that it is complex and substantial (Kengni *et al.*, 2001).

Vegetative propagation and stockplant management

The vegetative propagation of elite trees is central to the domestication strategy for indigenous trees producing valuable and marketable products (Leakey and Akinnifesi, 2008). A key element of this strategy is that the domestication is done by local people in their communities so that they are the beneficiaries of their work. This means that the vegetative propagation techniques have to be appropriate for implementation in remote villages by people with little, if any, formal education. For this reason, the techniques must be simple, robust, and must not be dependent on an electricity supply or running water. The achievement of this has been described by Leakey (this volume and 2004). One aspect of this is the way in which stockplants are managed. Thus, the long-term success of a cloning program is heavily dependent on the nursery management and the skills of the nursery staff.

Nursery management

Good nursery management involves many skills and attention to detail. The process starts with acquisition of high-quality germplasm of known origin (accession records) and recorded genetic quality, supported by documents recognizing the rights of the supplier (Access and Benefit Sharing agreements) – for example, see the Agroforestry Tree Genetic Resources Strategy of the World Agroforestry Centre (ICRAF, 2012). Furthermore this germplasm must have been appropriately stored and handled to avoid loss of viability. Germplasm can be of two types: seeds and vegetative propagules. Seeds also are of two main types: those that can be stored by drying or freezing (orthodox) and those which cannot be (recalcitrant). Both the latter and the vegetative propagules are short lived (from a few days to at most a few weeks). They have to be very carefully and rapidly handled to avoid water or temperature stress and any physical damage.

Accession records must be stored safely and the origin of every plant in the nursery must be labeled or in some other way traceable back to these records. Plants of unknown origin are of zero importance in a domestication program.

Successful plant production is dependent on rapid germination of seeds and propagation of vegetative propagules and their subsequent growth in good, free-draining potting compost well supplied with nutrients and organic matter. During early growth, some shade is usually desirable to prevent wilting and water stress. Usually, daily watering is required during dry weather. Once growing in the nursery, potted plants must be regularly maintained so that they do not become root bound and consequently the roots do not escape from the pot into the soil below (if this happens, it is very difficult to subsequently establish this plant as its roots will be left in the nursery). Plants should not be kept in the nursery so long that their root systems become coiled. Attention should be paid to weeds and pests.

Plants which are poorly managed in the nursery usually struggle to perform well once planted out in the field. The standards of nursery management are clearly visible to a visitor and are an excellent indicator of the interest and enthusiasm of the nursery staff and manager. Consequently, they are also a good indicator of the likely success of the subsequent planting program.

Predictive test for domestication of timber trees by vegetative propagation

One of the difficulties facing anyone involved in tree domestication is their longevity and long regeneration cycle. Many trees do not reach sexual maturity for 10–20 years and especially in the case of timber they do not display their yield potential and commercially important qualities until they are large trees. This makes tree breeding a slow business, but it also means that clonal forestry is difficult as juvenile trees which have not had time to display their potential are the easiest to propagate by cuttings. To get around this problem, large trees can be felled and allowed to develop coppice shoots, although this too is less likely from very old trees.

In *Triplochiton scleroxylon*, a West African timber tree conforming to Rauh's Model of branching architecture, a technique to predict which seedlings in a given population were more likely to grow to form the trees with the best form (branching frequency) and yield has been developed (Leakey and Ladipo, 1987; Ladipo *et al.*, 1991). This is based on the fact that the trees developing the greatest stem volume had been found to be those producing a few branches in each branch whorl and no branches between whorls – so allocating biomass to stem rather than to branches. The technique is based on an assessment of the 'strength' of apical dominance, the process regulating the formation of branches, by decapitating young seedlings and following the pattern of sprouting and the reassertion of dominance by the upper shoot (Ladipo *et al.*, 1992). This nursery-based screening technique in seedlings on 3–6 months old allows the rapid selection of those likely to produce the best stems to enter a program of clonal propagation. Conversely, because the leaves of this species are eaten as a vegetable by local people in Nigeria, the trees producing the most branches can be selected and managed as a hedge for leaf production.

Nursery management strategy

Farmers who manage tree nurseries can adapt their management to best meet their needs. For example, if their priority is to meet their own domestic food demands, they can plant the majority of the trees they produce in their own farm rather than selling them or multiplying them up by harvesting successive batches of cuttings or scions. Alternatively, if income

generation through the development of a tree nursery business for the sale of plants to other farmers is the priority, they can take 3–4 crops of cuttings off every plant per year for a few years and so very rapidly build up a large stock of plants for sale. This strategy should result in the greatest income generation in the long term but has the disadvantage that there are no financial returns in the first few years. An even longer term commercial strategy would be to do a long period of plant multiplication before large-scale planting. In addition to these individual strategies, there are, certainly, many possibilities of intermediate or mixed options.

Environmental Components of the Techniques

As a low-input farming system based on long-lived perennial trees, agroforestry provides many environmental benefits. Tree domestication is normally an approach to make these farming systems more productive and more profitable – in other words to intensify the agroforestry system. Many aspects of this will also have indirect environmental benefits in more rapid cover of the soil, greater root penetration, and lateral spread with consequently better protection and improvement of the soil and agroecosystem function. Rapid tree growth is associated with high water use. Although this may have negative impacts on the growth of associated crops, it can also reduce the impacts of salinization by lowering the water table.

Recent data in *Dacryodes edulis* show that vegetatively propagated cultivars have lower fine root density in the crop rooting zone and hence are more likely to be less competitive with crops (Asaah *et al.*, 2012). In addition, the perennial nature of trees also assists in carbon sequestration for the mitigation of climate change, and emerging evidence suggests that vegetatively propagated cultivars store more carbon than seed propagated individuals in their primary roots and shoots – an unexpected benefit of tree domestication (Asaah, 2012).

One important aspect of these environmental impacts is their quantification. This requires Baseline surveys based on randomized controlled trials – described by Barrett *et al.*, (2010) as providing solutions to development economics issues with weak causal factors. If applied to agroforestry, this approach should help to determine the scale of the impact at the plot, farm, landscape, and regional level.

Social Components of the Techniques

To maximize the social and economic benefits flowing from tree domestication, a participatory approach has been taken by the World Agroforestry Centre and some other organizations and their local partners to identify the farmers' preferences in terms of the tree species they would like to cultivate. Interestingly, in most of the places around the world where this has been done, the farmers have identified indigenous fruits, nuts, and leaves for uses as foods or medicines (Franzel *et al.*, 2008). As mentioned in the Section Social Components of the Strategy, participatory domestication has typically followed the identification of priority species, with farmers contributing their knowledge about the traits they would like to see incorporated within a selection program and the usefulness of the tree products to local households.

Figure 6 A village satellite nursery in Bangoua, Cameroon.

To encourage and assist the farmers, the agroforestry scientists and NGO partners in Cameroon have provided training and knowledge through specially constituted Rural Resource Centers in pilot villages in different regions of the country (Tchoundjeu *et al.*, 1998, 2006, 2010; Asaah *et al.*, 2011). These Rural Resource Centers provide opportunities for hands-on training in critical nursery management, vegetative propagation, agroforestry practices, and enterprise development in a community nursery (**Figure 6**). The focus of this training is that it is appropriate for implementation in often remote village nurseries without piped water and electricity. The farmers are then encouraged to set up similar facilities in their own farm or community, thus creating satellite nurseries which help to spread the techniques and concepts to neighboring communities. To encourage this kind of farmer-to-farmer technology transfer, exchange visits, demonstrations, and competitions covered by radio and television are organized. In time, these village and community nurseries become self-sufficient and independent.

In recent years, the range of topics presented in training programs has been expanded to include the wise use of microfinance and financial management, product marketing, business development, infrastructure development, and community organization. In parallel to this, artisans in neighboring towns have been trained in the fabrication of simple equipment and tools for product drying, processing, and packaging, whereas entrepreneurs and women's groups have been helped to develop businesses in food product processing and value adding aimed at improving the quality of products for the marketplace and increasing market demand. As these processes expand, it is expected that some people will cease to be farmers and producers and instead enter the cash economy as business men and women providing employment to others and developing new enterprises.

Although much progress has been made in developing, implementing, and expanding the participatory domestication of a wide range of agroforestry trees and commercializing their products, there is still much to do to quantify the socioeconomic impacts. A critical component of this is the establishment of statistically viable baseline surveys so that accurate assessments can be made in years to come as the concepts are disseminated and scaled up to new communities. This process

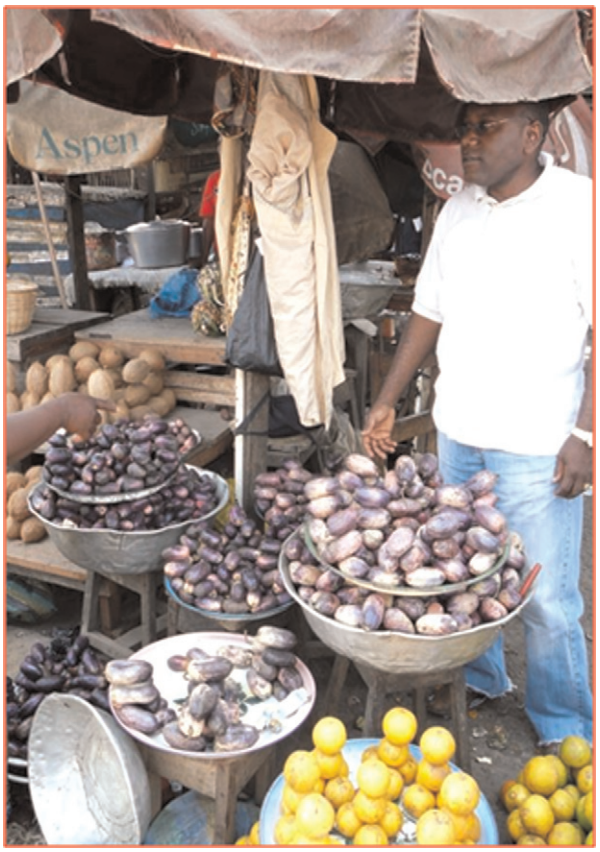

Figure 7 A market stall in Makanéné in Cameroon, selling *D. edulis* fruits.

has begun, but to date, the results are preliminary. Likewise, it is still too early to say much about the implementation of work to recognize and protect the rights of farmers and rural entrepreneurs to their innovations.

Commercial Components of the Techniques

Ultimately, as it can be seen from Figure 4, it is the commercialization of the sustainably grown products that potentially delivers the really important impacts from agroforestry and multifunctional agriculture. However, it is also recognized that commercialization can pose the greatest risks affecting the success or failure of the overall initiative. One study (Wynberg *et al.*, 2003) has examined the 'Winner or Loser' qualities of different approaches to the commercialization of an indigenous fruit (*Sclerocarya birrea* – Marula) in southern Africa (Table 1). It basically found that bottom-up community initiatives had the greatest chance of being Winners, although top-down commercialization involving large multinational companies could also be Winners if the company recognized the importance of buying raw products from local smallholder producers, rather than from large-scale plantation growers.

Focusing first on tree domestication can encourage the positive aspects of commercialization from producers practicing agroforestry. The expansion of markets beyond the traditional market or roadside stall (Figure 7) requires increased product quality, uniformity, and regular supply. The longer the value chain from local to global market, the more important are the attributes of quality, uniformity, and regularity of supply (Figure 8). Hence, the development and cultivation of vegetatively propagated cultivars selected for year-round

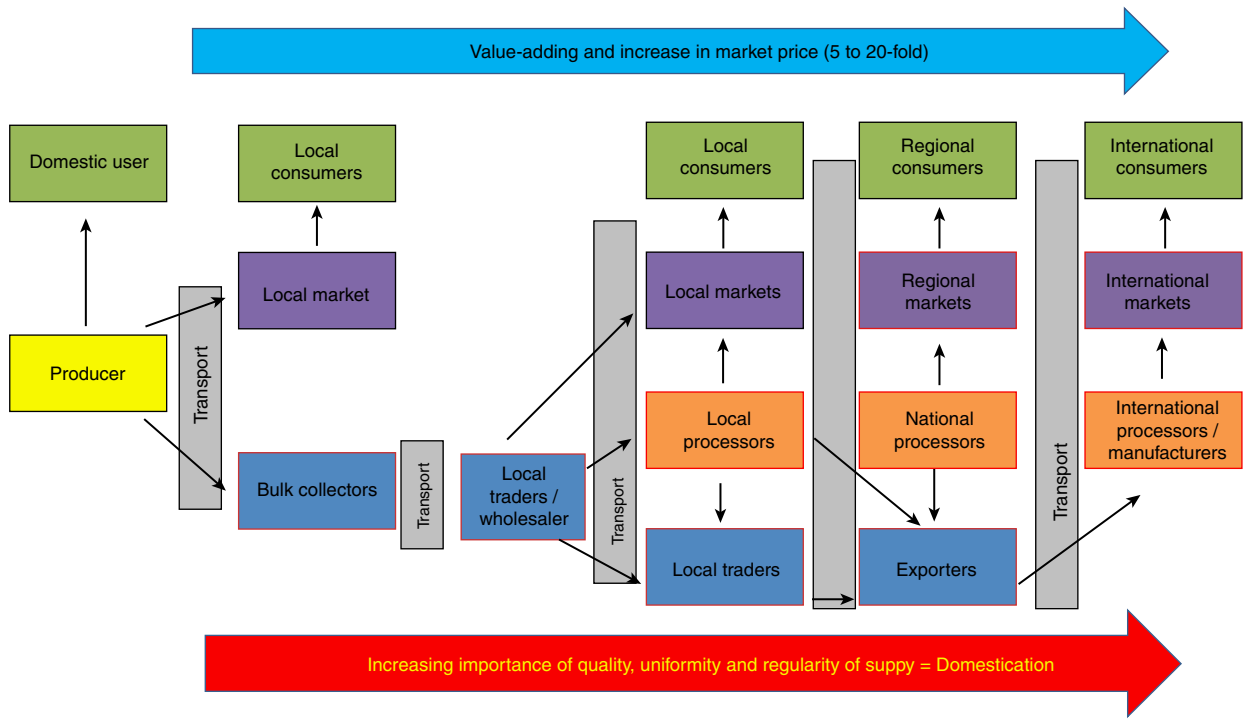

Figure 8 The increasing importance of domestication in the value chain of an agroforestry tree product.

production and other commercially desirable traits makes a quantum leap in the marketability of the products, as it means that traders and wholesalers can purchase a large volume of uniform, high-quality product from a recognized and named cultivar. In return, hopefully the producer will receive a higher price, as it is clear that consumers are willing to pay more for the more desirable varieties (**Figures 9** and **10**).

The above demand for uniformity and quality makes the ideotype concept more important, especially at upper end of the value chain where processing and value addition increase the value of the marketable products (**Figure 11**). With the increasing importance of the ideotype, the identification of the specific traits that confer market acceptability and market exclusivity and distinctiveness become more and more critical. This, therefore, is the reason for increasingly sophisticated research, mentioned in the Section 'Biological components of the technique' earlier, to determine the genetic variation found in different tree populations in the chemical, physical, and medicinal properties of the raw products. This, certainly, will lead to the need for stronger linkages between agroforestry researchers and partners in industry (Leakey, 1999b).

Food crop domestication over thousands of years has been credited with the advance of civilization as witnessed in industrialized countries (Diamond, 1997). However, domestication and commercialization are both part of this force for development, as one is considerably weakened without the other. Leakey (2012b,d) has recognized that in the tropics there is a need for a 'new wave of domestication,' but this too has to be supported by market growth along the value chain. Thus, one of the important components in this 'new wave' is the processing and value addition that extends the shelf life of products, expands market demand, and makes them more valuable. In Cameroon, the development of cottage industries to dry and package AFTPs has started (Asaah *et al.*, 2011), but this enterprise development and its up-scaling needs considerable expansion – recognizing the characteristics of Winners in the development process (**Table 1**). In this regard, one interesting development in recent years has been the involvement of a few multinational companies in Public–Private Partnerships with rural communities engaged in production of agroforestry products in tropical countries (Jamnadass *et al.*, 2011; Leakey, 2012b). Although associated with risks, this also offers great opportunities for the future development of agroforestry tree crops if the strategies and practices can be developed appropriately.

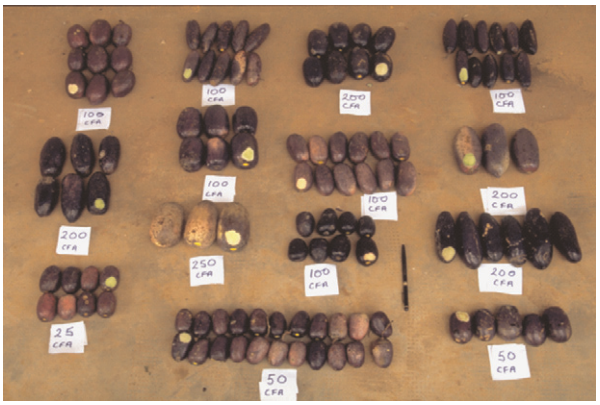

Figure 9 Fruits of *D. edulis* from market stalls showing the retail price in Central African francs (CFA) and illustrating consumer preferences for fruits from certain trees. Outcomes

To date, studies on the environmental and socioeconomic impacts of tree domestication have not been based on randomized controlled trials. Nevertheless, comparisons based on household surveys have indicated that integrated rural development based on agroforestry, tree domestication, and local market initiatives with small-scale enterprises have

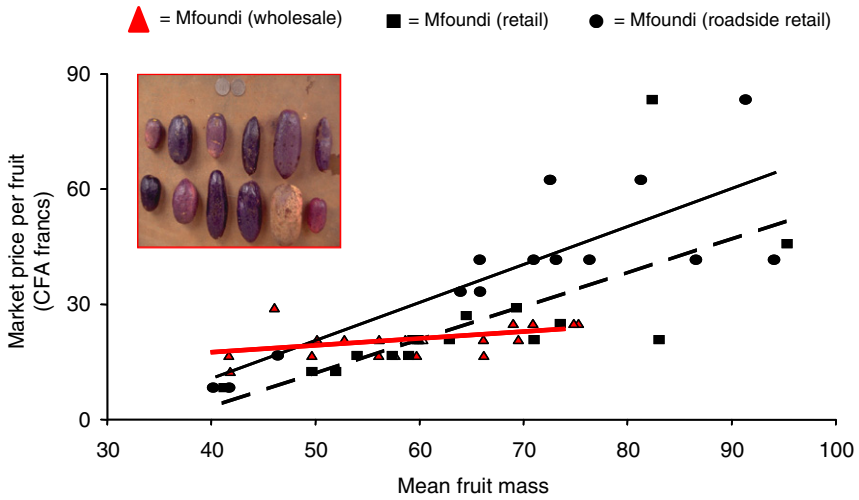

Figure 10 Relationship between mean *D. edulis* fruit mass and market price per fruit ($1 = 750CFA francs). Modified from Leakey, R.R.B., Atangana, A.R., Kengni, E., *et al.*, 2002. Domestication of *Dacryodes edulis* in West and Central Africa: Characterisation of genetic variation. Forests, Trees and Livelihoods 12, 57–71.

Figure 11 Value-added products developed from agroforestry tree species. Reproduced from Leakey, R.R.B., 2012b. Living with the Trees of Life – Towards the Transformation of tropical Agriculture. Wallingford, UK: CABI, 200 pp.

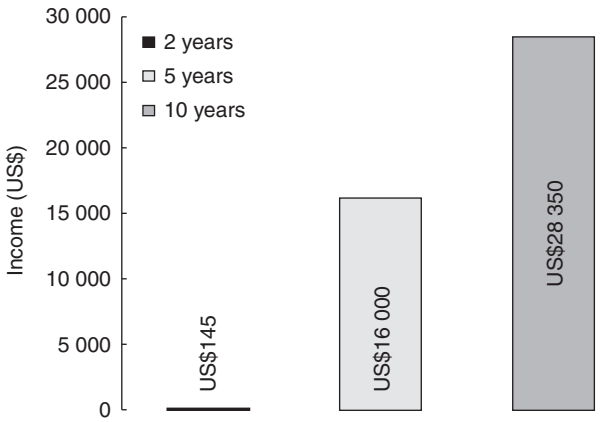

Figure 12 Income generated from plant sales at Rural Resources Centers in Cameroon after 2, 5, and 10 years. Reproduced from Leakey, R.R.B., Asaah, E.K., 2013. Underutilised species as the backbone of multifunctional agriculture – The next wave of crop domestication. Acta Horticulturae 979, 293–310.

positive impacts on the lives of farming households in participating communities (Figure 12 and Table 2). Together these impacts illustrate that agroforestry can deliver what the International Assessment of Agricultural Knowledge, Science and Technology for Development (IAASTD) called Multifunctional Agriculture (Table 3). Currently, the impacts are only on a local/household/farm/village scale and there is much to be done to upscale and outscale the agroforestry initiatives before the scales are extended (Table 4).

Biological Components of the Outcomes

The major outcome of participatory tree domestication, as expected, is new tree crop cultivars with improved product quality and greater market demand. This is happening in many places around the tropics in more than 50 species but is most advanced in Cameroon, where these cultivars have been developed by local farmers for cultivation in their own farms to meet household needs. However, as the supply of product increases, it is expected that both these cultivars and their products will be sold – at first locally and then more widely (Tchoundjeu *et al.*, 2010; Asaah *et al.*, 2011; Leakey, 2012b). The cultivation of these new cash crops is leading to the diversification of farming systems and this is expected to result in healthier agroecosystems. Another biological finding with likely impacts on agroecosystems is that vegetatively propagated trees allocate their dry matter differently, with less in fine root and more in primary roots and shoots. Consequently, clonal cultivars are more likely to be less competitive with annual crops (Asaah, 2012; Asaah *et al.*, 2010, 2012).

Environmental Components of the Outcomes

One important outcome expected from more sustainable land use systems that rehabilitate degraded land is better access to productive land for staple food crop production and hence the opportunity to diversify into other crops with market potential. This diversification either as mixed cropping or as landuse mosaics should improve the agroecosystem functions and thus lower the need for inputs such as pesticides. The increased tree

Table 2 The social, marketing, and natural resource qualities that determine whether or not the impacts of commercializing indigenous fruits, nuts, and other tree products are positive or negative

Winner qualities	*Loser qualities*
In individuals, households, and enterprises	
• Individuals organized as a group	• Poorly organized group structure
• Well informed about markets	• Poorly informed of markets
• Good access to transport	• Poor access to transport
• Coordinated production	• Uncoordinated production
• Small 'Input cost:Revenue received' ratio	• Large 'Input cost:Revenue received' ratio
• Consistently good quality products	• Variable quality products
• Skilled in bargaining	• Unskilled in bargaining
• Well networked with good partnerships	• Poorly networked
• Easy and equitable access to resource	• Uncertain and restricted access to resource
• Fits with other livelihood strategies and sociocultural norms	• Competes with other livelihood strategies and sociocultural norms
In product marketing	
• Commercial opportunities	• Undeveloped/poor market interest
• Diversity of end markets	• Limited markets
• Diversity of end products	• Fad or single niche products
• Positive marketing image	• No or negative marketing image
• Unique characteristics of product	• Many other substitutes
• Raw product quality well matched to market	• Raw product requires processing
• Many buyers of raw materials and products	• A monopsony – only one buyer of raw materials
• Many sellers of raw materials and products	• A monopoly – only one seller
• Buyers aware of product or brand	• Buyers ignorant of product or brand
In the tree resource	
• Abundant resource	• Rare resource
• Plant part used is readily renewable	• Slow replacement of harvested product
• Harvesting does not destroy the plant	• Destructive and damaging harvesting
• Easily propagated	• Difficult to propagate
• Genetically diverse with potential for domestication	• Genetically uniform or little potential for selection
• Multiple uses for products	• Narrow use options
• High yield of high-quality product	• Low yielding and/or poor-quality product
• Valuable product	• Low-value product
• Consistent and reliable yield from year to year	• Inconsistent and unpredictable production
• Already cultivated within farming system	• Wild resource which is difficult to cultivate
• Already being domesticated by local farmers	• Totally wild resource
• Fast growing	• Slow growing
• Short time of production of product	• Long time to production
• Compatible with agroforestry land uses	• Competitive with crops, labor intensive, etc.
• Hardy	• Sensitive to adverse environmental conditions
• Widely distributed	• Only locally distributed

Source: Reproduced from Leakey, R.R.B., Tchoundjeu, Z., Schreckenberg, K., Shackleton, S.E., Shackleton, C.M., 2005. Agroforestry tree products (AFTPs): Targeting poverty reduction and enhanced livelihoods. International Journal in Agricultural Sustainability 3, 1–23.

cover, especially if arranged along the contours of hillsides, protects the soil and reduces the risks of serious erosion and can also protect watersheds. The hydrological impacts are most fragile in dryland environments.

The perennial nature of trees also assists in carbon sequestration for the mitigation of climate change, and emerging evidence suggests that vegetatively propagated cultivars store more carbon in their primary roots and shoots than by seed-propagated individuals – an unexpected benefit of tree domestication (Asaah, 2012).

Social Components of the Outcomes

One of the original purposes of initiating participatory tree domestication was to improve the livelihoods of poor farmers, especially income generation to reduce poverty; food security to reduce hunger; better nutrition and diet to reduce malnutrition; and better equity to improve the lot of women and children in society. It was envisioned that indirectly this would also improve health and education opportunities and that the overall package would empower individuals and communities, allowing them to be more self-sufficient in order to transform their lives, giving them hope for the future. Early indications (Table 2) are that these outcomes are starting to emerge in the participating communities. Furthermore, when associated with microfinance, business training and access to simple equipment for the processing and packaging of raw products, there is now evidence of rural people engaging in small businesses either as entrepreneurs or as employees.

Table 3 The impacts reported by farmers engaged in a participatory domestication program for agroforestry trees in Cameroon

Positive impacts
Increased number of farmers adopting agroforestry and the domestication of indigenous trees
Increased production of tree products
Increased income from tree sales by nurseries
Increased income from sale of tree products
Increased income from better farming practices
Increased income from eligibility for microfinance
Increased income used for schooling and school uniforms
Increased income used for medicines and healthcare
Increased income used for home improvements – for example, installation of water and electricity in the home, new buildings, etc.
Increased income used for farm improvement – for example, livestock, wells, agricultural inputs, etc.
New employment opportunities from nurseries
New employment opportunities from processing both agricultural crops (such as cassava) and new markets for processed agroforestry products (fruits, spices, herbs, and medicinals)
New employment opportunities in the emerging workshops producing small tools and appropriate mechanized equipment to service the need for food processing equipment
New employment opportunities from marketing as traders of processed products and the food processing equipment
New employment opportunities in transport from producers to markets and to the processors of agricultural produce
Retention of youths in the villages due to career opportunities by domesticating trees in their village nurseries
Tree domestication has led to better diets and improved nutrition
Luxury food items consumed
Improved health from potable water
Piped water supplies for irrigation and use in nurseries
Increased livestock rearing due to tree fodder
Increased use of traditional medicines and better health
Increased honey production and processing
Reduced drudgery in women's lives from not having to collect water from rivers and farm produce from remote farms, as well as from mechanical processing of food crops
Reduced drudgery gives more time to look after their families and engage in farming or other income-generating activities
Improved marketing for food and agroforestry products
Improved soil fertility from improved fallows has increased crop yields 2- to 3-fold with better weed control
Improved tree fodder for goats and cattle
Having more time as a result of better farming methods, farmers had more time for marketing and new farming activities
Community feeling empowered, stronger, and optimistic for the future in ways that they could sustain
Knowledge has empowered the Rural Resource Centers as an agent of change
Negative impacts
Increased jealousy and theft
New roads lead to deforestation and land degradation as a result of the expansion of farming activities to more remote areas

Significantly, one of the outcomes mentioned by young people in the participating communities is that this now means that they can see a future for themselves if they remain in the village rather than feeling that they have to migrate to towns and cities for a better life (Table 2).

Table 4 The characteristics of the participatory domestication of agroforestry trees important for the delivery of multifunctional agriculture

The features that agroforestry brings to multifunctional agriculture to enhance social, economic, and environmental resilience in agriculture and rural development are:

- Based on TK and culture
- Based on participatory techniques to ensure relevance to local people
- Based on integrated natural resources management and sustainable land use
- Based on knowledge of the natural resource

The above features mean that multifunctional agriculture can:

- Empower subsistence farmers to control their destiny
- Enhance food security and rural/urban livelihoods, reducing hunger
- Enhance nutrition security and health, reducing malnutrition and diseases
- Enhance opportunity for income generation, reducing poverty
- Diversify farming system at the local and landscape scale, enhancing watershed services and sustainable production
- Create new agricultural commodities
- Diversify market economy and buffer commodity price fluctuations
- Decentralize business opportunities to the villagers
- Create employment in processing and marketing
- Build social responsibility from the 'grassroots'
- Enhance international public goods and services, reducing climate change and loss of biodiversity
- Offer opportunities for new policy interventions to combat deforestation, desertification, and land degradation
- Breakdown the disconnects between disciplines and organizations responsible for policy and its implementation in rural development

Source: Reproduced from Leakey, R.R.B., 2012b. Living with the Trees of Life – Towards the Transformation of tropical Agriculture. Wallingford, UK: CABI, 200 pp.

Commercial Components of the Outcomes

The important commercial outcomes have been the development of Rural Resource Centers that deliver both education and training in agroforestry and tree domestication, as well as in community development and business management so that the villagers can earn money from the sale of plants and raw products. This money is then being used to make infrastructure developments, such as roads and clean water supplies, as well as to reduce the drudgery of the women (Table 2). The consequence of this has been that poor farmers are starting to generate income and enter the cash economy and so begin to climb out of poverty (Figure 11). In bigger villages and small towns, local people are also developing cottage industries and engaging more in marketing and trade. This relationship between enhanced farm production and urban life is important for the rural economy and the overall alleviation of poverty. It is an example of farm production being the 'engine of growth.'

Future Impact

In the long term, the application of these strategies should lead to benefits, which encompass many of the rural development goals of development agencies, as specified in the Millennium Development Goals of the United Nations. At the community

level, some of these goals have been achieved, but to date, it is still only talked about several thousand participating farmers. Achieving these benefits will, however, require the large-scale adoption of the techniques and strategies presented here in ways that will meet the needs of the farmers and those of new and emerging markets (Leakey *et al.*, 2012). This makes it important to get the messages about good domestication strategies to policy makers (e.g., Wynberg *et al.*, 2003).

Clearly, the challenge is to scale up the application of agroforestry and tree domestication to the huge numbers needed to have meaningful impact of national, regional, and global scales.

Biological Components of the Impact

The vision of what could be achieved with the widespread adoption of the domestication of trees and the associated trade of the products in numerous different industries is perhaps best exemplified by the domestication of the wolf to give large numbers of breeds of dogs of all sorts of shapes, sizes, and appearances, to be both pets and working partners with farmers, policemen, entertainers, blind people, etc. These dog breeds have arisen by breeders teasing out the genetic traits present in the wolf genome. If the same is done for trees, there could be a large number of different cultivars meeting the needs of many food, cosmetic, medicinal, perfume, fiber, and wood markets – not just in one species but in hundreds of species. This, in turn, would lead to a highly diversified, intensified, and more productive Multifunctional Agriculture (Leakey, 2012b).

Integrated Environmental, Social, and Economic Components of the Impact

The restoration of degraded land by Multifunctional Agriculture could make productive land available for an expansion of overall farm production to fill the Yield Gap (Leakey, 2012b) and meet the needs of a growing human population without the need for further deforestation and without future negative impacts on erosion, flooding, climate change, etc. A healthier environment could lower the risks of disasters due to flooding, drought, landslides, pest and disease epidemics, etc.

The achievement of even greater success than foreseen by the Millennium Development Goals could lead to greatly improved local and national economies and the gradual transition of developing countries toward developed countries.

Glossary

Agroforestry Purposeful growing of trees, crops, sometimes with animals, in interacting combinations for a variety of objectives. Agrisilviculture = trees + crops; Silvopasture = trees + pasture/animals; Agrosilvopasture = trees + crops + animals/pasture.

Alley cropping Growing crops in the interspaces between rows of planted trees or shrubs. In the tropics, crops are grown in the alleys between trees or regularly pruned hedgerows of planted, usually nitrogen-fixing, shrubs or trees. In temperate zones, crops are grown in the alleys of widely spaced timber trees.

Community forestry A form of social forestry, where tree-planting activities are undertaken by a community of people on common or communally owned land.

Fallow Land resting from cropping, which may be grazed or left unused, often colonized by natural vegetation. An improved fallow refers to deliberate planting of fast-growing species for rapid replenishment of soil fertility.

Farm forestry Tree planting on farms, usually as woodlots.

Homegarden A subsistence farming system consisting of integrated mixtures of multipurpose trees and shrubs in association with crops and sometimes livestock around homes, the whole unit managed intensively by family labor.

Multipurpose tree (and shrub) A tree/shrub that is grown for multiple products and/or services.

Multistoried or multistrata system An arrangement of plants forming distinct layers from the lower (usually herbaceous) layer to the uppermost tree canopy.

Social forestry Tree planting to pursue social objectives.

Introduction: A Brief History of the Development of Agroforestry

Agroforestry is perhaps as old as agriculture itself. The practice has been prevalent for many centuries in different parts of the world, especially under subsistence farming conditions. For example, homegardening is reported to have been associated with fishing communities living in the moist tropical region approximately 10 000 BC (Kumar and Nair, 2004; Nair and Kumar, 2006), and in Europe, domestic animals were introduced into forests to feed approximately 4000 BC (Mosquera-Losada *et al.*, 2012). It has, however, been only during the past 35 years that these indigenous forms of growing trees and crops/animals together were brought under the realm of modern, scientific land-use scenarios.

Several factors contributed to the above-stated development. When the newly independent nations of the developing world were faced with the problem of feeding their millions during the 1950s and 1960s, the policy makers thought the best solution was to focus on the model of modern intensive monocultural agriculture that was successful in the industrialized world. Several food-production technologies were consequently developed with emphasis on production of preferred species of crops in monocultural or sole-crop stands with heavy input of agrochemicals (fertilizers, insecticides, herbicides, etc.), mechanization, and irrigation. In the 1970s, these efforts, collectively called the Green Revolution, resulted in substantial gains in food production and helped avert large-scale hunger in some regions of the world. At that time, most of the international agricultural research centers (IARCs) of the Consultative Group on International Agricultural Research (CGIAR) system and the national programs focused on a few individual food crops and their production technologies for sole-crop production systems. However, for a variety of reasons, many farmers, especially the poorer ones in the tropics and subtropics, were often continuing their traditional practices of cultivating crops in mixed stands for more than one season, and were commonly nurturing trees in their cropping systems. In such circumstances, the production technologies developed for individual crops were not wholly applicable to these systems. Similar patterns of single-species stands of trees were also adopted in plantation forestry and fruit orchards in many parts of the tropics and that resulted in significant gains in wood and fruit production. Typically, the traditional, mixed production systems of raising food crops, trees, and animals together as well as exploiting a multiple range of products from natural woodlots did not fit into this 'modern' single-commodity paradigm, and were discouraged. Serious doubts began to be expressed in the 1960s and 1970s about the relevance of the single-commodity strategies and policies promoting them. In particular, there was concern that the basic needs of the poorest farmers were neither being considered nor adequately addressed. Soon it became clear that many of the technology packages that contributed to the Green Revolution, such as irrigation systems, fertilizers, and pesticides, were not affordable by the poor farmer on the one hand, and their large-scale application had serious environmental consequences on the other. It was also recognized that most tropical soils, which are poorer and more easily degraded than temperate-zone soils, were unable to withstand the impact of high-input technologies. The disastrous consequences of increasing rates of deforestation in the world's tropical regions also became a matter of serious concern. It was clearly understood that a major cause of deforestation was the expansion of agricultural land to provide food and fuelwood for the rapidly increasing populations. Faced with these problems, land-use experts and institutions intensified their search for appropriate strategies that would be socially acceptable, enhance the sustainability of the production base, and meet the need for production of multiple outputs. These collective efforts led to taking a new look at the age-old practices based on combinations involving trees, crops, and livestock on the same

 doi:10.1016/B978-0-444-52512-3.00021-8

land unit. The inherent advantages of traditional land-use practices involving trees – sustained yield, environmental conservation, and multiple outputs – were recognized quickly. Agroforestry thus began to come of age in the late 1970s. The establishment of the International Council (Centre, since 1991) for Research in Agroforestry (ICRAF), now known as the World Agroforestry Centre, in 1977, in Nairobi, Kenya, signified the institutionalization of agroforestry and heralded the beginning of the era of agroforestry as a multidisciplinary science (Nair and Garrity, 2012).

In the temperate, industrialized regions, the evolution of 'modern' agroforestry was slower than in the tropics. J. Russell Smith's classical work Tree Crops: A Permanent Agriculture (Smith, 1950) is considered to have created a 'new' wave of interest in agroforestry; he argued that "an agricultural economy based almost entirely upon annual crops such as corn and wheat is wasteful, destructive of soil fertility and illogical." However, it was not until the late 1970s to early 1980s that the push for ecologically and socially friendly management approaches such as integrated natural resource management, the principles of which are encompassed in agroforestry, gathered momentum. It started with the understanding about the undesirable environmental consequences of high-input agriculture and forestry practices that focused solely on the economic bottom line (Brown, 2004). Their demand for environmental accountability and application of ecologically compatible management practices increased when it became clear that the land-use and land-cover changes associated with the removal and fragmentation of natural vegetation for establishment of agricultural and forestry enterprises led to adverse ecological consequences (Garrett, 2009). Agroforestry initiatives have also sprung up and moved forward in several industrialized regions of the world including Europe (Rigueiro-Rodriguez *et al.*, 2008; Mosquera-Losada *et al.*, 2012) and Australia and New Zealand (Polglase *et al.*, 2008).

Agroforestry: Concepts, Principles, and Characteristics

Agroforestry is a loosely defined term. Several definitions – long and short – and descriptions have been proposed for agroforestry, and innumerable discussions have taken place in professional and technical meetings and conventions on the definition quagmire, especially during the early stages of the development of the discipline in the 1970s and 1980s. Over time, the enthusiasm to define and describe the term subsided. A consensus has since emerged that agroforestry is one of the terms – including agriculture, forestry, and several subsets within them – that cannot be defined exactly, and that the concept is more important than the definition.

At present, there is a general understanding that agroforestry refers to the purposeful growing of trees and crops in interacting combinations for a range of objectives including both a variety of products or commodities and a vast array of environmental and other ecological services. Basically, it involves the deliberate admixture of trees and shrubs, collectively called woody perennials or trees, on the same unit of land as agricultural crops or animals, either in some form of spatial arrangement or temporal sequence. In the resulting systems, there is significant ecological and economical interaction between the woody and the nonwoody components. Thus, an agroforestry system normally involves two or more species of plants (or, plants and animals), at least one of which is a woody perennial. The system has two or more outputs and a production cycle of more than 1 year, and both its ecology and economics are more complex than in a monocultural system of agriculture or forestry. Gold and Garrett (2009) describe the essence of agroforestry in four key 'I' words: intentional, intensive, interactive, and integrated. The term 'intentional' implies that systems are intentionally designed and managed as a whole unit, and 'intensive' means that the systems are intensively managed for productive and protective benefits. Toward this end, it has been argued that agroforestry intensification involves the inclusion of genetically superior (domesticated) trees (Leakey, 2012a). The biological and physical interactions among the system's components (tree, crop, and animal) are implied in the term 'interactive,' and 'integrative' refers to the structural and functional combinations of the components as an integrated management unit. It is often emphasized that all agroforestry systems (AFS) are characterized by three basic sets of attributes: productivity (production of preferred commodities as well as productivity of the land's resources), sustainability (conservation of the production potential of the resource base), and adoptability (acceptance of the practice by the farming community or other targeted clientele). These different concepts of agroforestry are captured in ICRAF's characterization: "Agroforestry is a dynamic, ecologically sound system of natural resource management. By integrating trees on farms and in the agricultural landscape, it helps diversify and sustain production for enhanced economic, environmental and social benefits" (World Agroforestry Centre, 2008).

As noted in the Section Introduction: A Brief History of the Development of Agroforestry, the motivations for initiatives in agroforestry research were different in the tropics and the temperate regions. Given that the structure and management of land-use systems are determined not only by the biological components, but also by the site-specific ecological features and the local social and cultural characteristics, such differences between the tropics and the temperate zones are common in all forms of land use, be it agriculture, including animal production, or forestry. These ineluctable differences manifest themselves in the nature, characteristics, objectives, and expectations of agroforestry practices in the two broad geographical regions; nevertheless, the practices in both regions encompass the same concepts and principles.

In addition to agroforestry, several other terms with 'forestry' endings became prominent in the late 1970s and 1980s as a consequence of increasing global interest in tree-planting activities. These include Community Forestry, Social Forestry, and Farm Forestry. Although these terms have also not been defined precisely, they emphasize people's participation in tree-planting activities, not necessarily in association with agricultural crop and/or animals as in agroforestry, but with the social objectives ranking equally in importance with production objectives. Social forestry refers to using trees and/or tree planting specifically to pursue social objectives, usually betterment of the poor, through delivery of the benefits of tree products and/or tree

planting to the local people. Community forestry, a form of social forestry, refers to tree-planting activities undertaken by a community on communal lands or the so-called common lands; it is based on the local people's direct participation in the process, either by growing trees themselves, or by processing the tree products locally. Farm forestry, a term used mainly in Asia, refers to tree planting on farms. The major distinction between agroforestry and these other terms is that whereas agroforestry emphasizes the interactive association between woody perennials and agricultural crops and/or animals for multiple products and services, the other terms refer to tree planting, often as woodlots. Several other terms and initiatives such as permaculture, agroecology, and farming systems that encompass the concept of integrated land use (with or without trees) have also become prominent since the 1970s. In practice, however, all these activities and practices that include trees directly or indirectly refer to growing and using trees to provide food, fuelwood, fodder, medicines, building materials, and cash income. Only blurred lines, if any at all, separate them, and they all encompass agroforestry concepts and technologies. Therefore, in common land-use parlance, these different terms are often used as synonyms, and sometimes out of context.

Agroforestry: Practices and Systems

A wide range of traditional land-use systems that fit the concept of agroforestry as outlined in the Section Agroforestry: Concepts, Principles, and Characteristics has been identified from different parts of the world (Nair, 1989) and others being practiced may still remain to be identified. The most organized effort to understand the complexity, diversity, and extent of indigenous AFS in the tropics has been a global inventory undertaken by ICRAF between 1982 and 1987. That activity was aimed at systematically collecting, collating, and evaluating data pertaining to a large number of such systems around the tropics (Nair, 1989). It assembled, for the first time, a substantial body of information on a large number of AFS including their structure and functions, and their merits and weaknesses. Based on this comprehensive database, Nair (1985; 1989) proposed a classification scheme for AFS based on several criteria:

1. Structure of the system: based on the nature and arrangement of the three major groups of components:
   a. Agrisilviculture (trees + crops).
   b. Silvopasture (trees + animals).
   c. Agrosilvopasture (trees + crops + animals).
2. Primary functions of the system:
   a. Production of basic needs such as food, fodder, fuelwood, and cash.
   b. Protection or service functions (such as soil fertility build-up, environmental amelioration, wind-protection, and erosion control).
3. Spatial arrangement of components, i.e., time sequence pattern of component arrangement:
   a. Simultaneous (trees intercropped with crops or livestock).
   b. Sequential (trees and crops rotated in sequence).
4. Level of management:
   a. Subsistence to commercial.
   b. Household consumption to market-oriented.

Other classification schemes of AFS have also been proposed (e.g., Sinclair, 1999); but essentially they are all based on the above criteria and concepts. Various characterizations and descriptions of AFS such as agrisilvicultural systems for fuelwood production in semiarid lands, silvopastoral systems for animal production in sloping lands, multistrata homegardens in humid tropics, etc., are common in agroforestry literature. Moreover, descriptions of existing systems as well as recommendations of potential agroforestry technologies for specific agroecological zones include a mixture of various forms of agroforestry in terms of the nature and arrangement of components, and several AFS can be found within the same ecological regions. Thus, in general, any specific agroforestry practice cannot be identified exclusively to a specific ecological region, and vice versa.

The nature, complexity, and objectives of agroforestry vary considerably between the tropics and the temperate region. **Table 1** presents a list of the major tropical practices. Local adaptations and manifestations of these (and other) practices exist as innumerable AFS with site-specific characteristics in different parts of the tropics and subtropics (Nair, 1989; 1993).

Compared with the tropics, agroforestry practices and systems in the temperate zone are less diverse and complex. The Association for Temperate Agroforestry (AFTA) has recognized five major agroforestry practices in North America: alley cropping, forest farming, riparian buffer strips, silvopasture, and windbreaks (**Figure 1**). Other temperate-zone AFS include the ancient tree-based agriculture involving a large number of multipurpose trees such as chestnuts (*Castanea* spp.), oaks (*Quercus* spp.), carob (*Ceratonia siliqua* L.), olive (*Olea europa* L.), and figs (*Ficus* spp.) in the Mediterranean region (Nair *et al.*, 2008; Rigueiro-Rodriguez *et al.*, 2008). The dehesa system, grazing under oak trees with strong linkages to recurrent cereal cropping in rangelands, is also a very old European practice (Rigueiro-Rodriguez *et al.*, 2008; Howlett *et al.*, 2011; Mosquera-Losada *et al.*, 2012).

AFS Subgroups

To further streamline AFS nomenclature and reduce the number of major groups, Nair (2012a) arranged the systems into five major subgroups with major types of AFS identified under each, as listed below. These are followed in this article:

1. Multistrata systems
   - Homegardens (including mixed fruit and spice tree gardens): Intimate multistory combinations of several trees – especially fruit- and nut-producing species – and crops in homesteads; livestock may or may not be present; the size of the garden is small (< 1 ha) and the garden is managed intensively usually by family labor.
   - Shaded perennials: Growing shade-tolerant species such as cacao (*Theobroma cacao* L.) and coffee (*Coffea* sp.) under or in between overstory shade-, timber-, or other commercial tree crops.
   - Other multistrata agroforests: Various other forms of complex multistrata agroforests and multilayer tree gardens exist in different tropical humid lowland regions of Southeast Asia and parts of Africa and Latin

Table 1 Major agroforestry practices in the tropics

Agroforestry practice	*Brief description*
Tropical agroforestry	
Alley cropping (hedgerow intercropping)	Fast-growing, preferably leguminous, woody species grown in crop fields; the woody species pruned periodically to a low height (<1.0 m) to reduce shading of crops; the prunings applied as mulch into the alleys as a source of organic matter and nutrients, or used as animal fodder.
Homegardens	Intimate multistory combinations of a diverse and large number of trees and crops in homesteads; livestock may or may not be present.
Improved fallow	Fast-growing, preferably leguminous, woody species planted and left to grow for short periods (2–3 years) of fallow between cropping periods for soil fertility enhancement; woody species may yield economic products.
Multipurpose trees (MPTs) on farms and rangelands	Fruit trees and other MPTs scattered haphazardly or planted in some systematic arrangements in crop or animal production fields; trees provide products such as fruits, fuelwood, fodder, and timber.
Silvopasture:	Integration of trees in animal production systems:
• Grazing systems	○ Cattle grazing on pasture under widely spaced or scattered trees.
• Cut-and-carry system (Protein banks)	○ Stall-feeding of animals with high-quality fodder from trees grown in blocks on farms.
Shaded perennial-crop systems	Growing shade-tolerant species such as cacao and coffee under or in between overstory shade-, timber-, or other commercial tree crops.
Shelterbelts and windbreaks	Use of trees to protect fields from wind damage, sea encroachment, floods, etc.
Taungya	Growing agricultural crops during the early stages of establishment of forestry (timber) plantations.

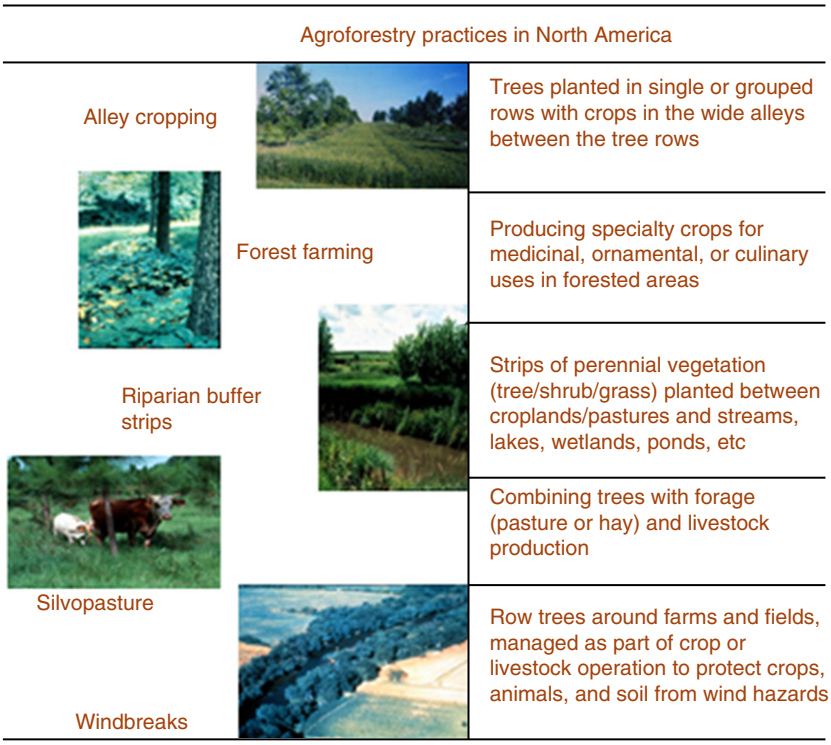

Figure 1 Agroforestry practices in North America.

America, involving a variety of tree species such as damar (*Shorea* spp.), cinnamon (*Cinnamomum zeylanicum*), and jungle rubber (*Hevea* sp.) that are exploited for their for nonwood products.

2. Tree intercropping
   - Alley cropping: Fast-growing, preferably leguminous, woody species grown in crop fields as a hedgerow with close (~0.5 m) in-row spacing and wide (4 m or more) between-row spacing; the woody species pruned periodically at low height (<1.0 m) to reduce shading of crops; the prunings applied as mulch into the alleys as a source of organic matter and nutrients, or used as animal fodder.
   - Multipurpose trees on farmlands: Fruit-, fodder-, fuelwood-, and timber trees scattered or planted in some systematic arrangements in crop- or animal-production fields.

3. Silvopasture (trees in support of crop production)
   - Grazing under scattered or planted trees.
   - Tree-fodder systems (fodder banks).
4. Protective systems
   - Boundary planting, windbreaks, shelterbelts, soil conservation hedges: Use of trees to protect fields from wind damage, sea encroachment, floods, etc.
5. Agroforestry woodlots
   - Block planting of preferred tree species for specific purposes such as reclamation of salt-affected lands, eroded lands, acid soils, waterlogged soils, etc.

Geographical Distribution and Area under AFS

The nature and intensity of the type of agroforestry practiced in a locality or region is determined primarily by its ecological potential and socioeconomic conditions. Humid lowlands and other tropical regions of the world that are not constrained by climatic limitations such as extreme temperatures and long dry seasons are home to a large diversity of plant species and therefore numerous and diverse AFS. Moreover, socioeconomic factors such as human population pressure, greater availability of labor, smaller land-holding size, complex land tenure, and lack of proximity to markets often support more and diverse AFS in such regions. In general, small family-farms, subsistence food crops, and emphasis on the role of trees in improving soil quality of agricultural lands are characteristic of tropical AFS. However, environmental protection is the main motivation for agroforestry in the industrialized nations, where intensive, mechanized monocultural production systems of agriculture and forestry have contributed to reduced biodiversity and loss of forest resources and wildlife habitat, and increased environmental hazards such as erosion, nonpoint source pollution of ground water and rivers, and greenhouse-gas emissions.

As noted above, multistrata systems (homegardens, shaded perennial systems, and multilayer tree gardens) are common in tropical regions with high human population, whereas less intensive systems are common in areas with lower population density. In the moist tropical and dry regions also, the nature of AFS is influenced by climate and population pressure: homegardens and multilayer tree gardens are found in the relatively wetter areas; tree intercropping systems such as multipurpose trees on crop lands, silvopastoral (grazing) systems, and protective systems of windbreaks and shelterbelts are common in these regions. In the tropical montane regions that have favorable rainfall regimes, sloping lands and rolling topography make soil erosion an issue of major concern; consequently, soil conservation is one of the main objectives of agroforestry in these regions. Shaded perennial systems, use of woody perennials in soil conservation, and silvopastoral systems are the major forms of agroforestry in such tropical highlands. Several other specific systems also exist in the tropics such as apiculture with trees, aquaculture involving trees and shrubs; but, again, information on them was too meager to warrant their inclusion here.

Estimating the area under AFS on a farm in itself is a challenge because of the lack of clarity and proper procedures for delineating the area influenced by trees in a mixed stand of trees and crops (Nair *et al.*, 2009). In simultaneous systems, the entire area occupied by multistrata systems such as homegardens and shaded perennial systems and intensive tree-intercropping situations can be listed as agroforestry. However, most AFS are rather extensive, where the components, especially trees, are not planted at regular spacing or density; for example, the parkland system and extensive silvopastures. Such situations exist also in Europe and other temperate regions where the mosaics of intensive field systems, with hedgerows and patches of woodland, are common features of agricultural landscapes. The problem of estimating the area under agroforestry is more difficult in the case of practices such as windbreaks and boundary planting where although the trees are planted at wide distances between rows (windbreaks) or around agricultural or pastoral parcels (boundary planting), because the influence of trees both above and below ground extends beyond the obviously visible area of trees. For windbreaks, the rule of thumb is that the area protected from wind erosion extends laterally to 10 times the height (H) of trees in the central core of windbreaks. The problem has a different dimension of difficulty when it comes to sequential tropical systems such as improved fallows and shifting cultivation. In such situations, the beneficial effect of trees and other woody vegetation (in the fallow phase) on the crops that follow them (in the cropping phase) is believed to last for a variable length of time (years). Despite these temporal and spatial issues, a recent ICRAF survey using high-resolution remote-sensing (Zomer *et al.*, 2009) quantified the areas of agricultural landscapes with at least 10% tree cover worldwide as nearly a billion hectares. Considering the prevalence of agroforestry practices in nonagricultural lands, Nair (2012a) estimated the global area currently or potentially under agroforestry as 1.6 billion ha (**Table 2**).

Brief Description of Major Agroforestry Practices

Intercropping (Alley Cropping and Other Forms of Tree Intercropping)

In the tropics, alley cropping was developed by researchers in the 1970s and 1980s in an attempt to find alternatives to the long-term fallows of shifting cultivation. The main motivation and rationale for alley cropping was the perceived soil-improving potential of fast-growing, leguminous woody species and their ability to withstand repeated cutting. It was hypothesized that by integrating these woody species into food crop production systems in simultaneous combinations, some of the benefits of natural long-term fallows such as recycling nutrients, suppressing weeds, and controlling erosion on sloping land could be realized without having to keep the land out of agricultural production. The practice consists of growing arable crops between hedgerows of planted shrubs and trees, preferably leguminous species that are periodically pruned to prevent shading to crops (**Figure 2**). The biomass obtained by pruning the trees and shrubs during the crop-growing season is put back to the alleys as a source of mulch and green manure. Besides, leguminous woody species add nitrogen to the system through biological nitrogen fixation.

Table 2 Global distribution and area under different agroforestry system subgroups[a]

AFS subgroup	*Major AF practices*	*Distribution (major agro-ecological/geographical regions)*[b]		*Approximate area (million ha)*[b]	
		Tropical	*Temperate*	*Tropical*	*Temperate*
Multistrata systems	Homegardens	Humid: wet, moist, and montane (rainfall >1000 mm year^{-1})	Forest farming	100	
	Shaded perennials				
Tree intercropping	Alley cropping	Rainfall >800 mm year^{-1}	n/a	50	50
	Trees on farmlands	Throughout tropics	n/a	550	50
Silvopasture	Cut-and-carry and browsing	Wet and moist; rainfall >1000 mm year^{-1}		300	150
	Grazing under trees	Semiarid to arid	North America, Europe, subtropical highlands		
Protective systems	Windbreaks, shelterbelts	Semiarid and arid lands; coastal areas	North America, Europe, China	200	100
	Soil conservation hedges	Sloping lands in higher rainfall areas	North America (Riparian buffer strips)		
	Boundary planting	Throughout	Windbreaks		
Agroforestry woodlots	Firewood and fodder	Drylands		50	
	Land reclamation	Degraded lands (eroded, salt-affected)			
Total				1250	350

[a]Estimates based on the reported values in literature.

Figure 2 Tropical alley cropping. Fast-growing, coppicing, nitrogen-fixing shrubs and trees are grown in rows 4–8 m apart in crop fields and pruned periodically (4–6 week intervals); the succulent and easily decomposable tree biomass so obtained is returned to the cropped alleys as a source of nutrient for crops. The photo shows *Gliricidia sepium* grown with maize (*Zea mays*), a practice followed by thousands of farmers in eastern and southern Africa. Photo credit: ICRAF, Nairobi, Kenya.

Many studies on alley cropping, of both biophysical and socioeconomic nature, were undertaken in various parts of the tropics during the 1980s and 1990s. Indeed, alley cropping was the most widely researched topic in tropical agroforestry during that period. In interpreting the results of these studies, some experts have used the data to defend alley cropping, others to denigrate it. But, the merits or demerits of alley cropping or, for that matter, any agroforestry technology cannot be judged on the basis of any single criterion or short-term result. Benefits other than crop yield, such as soil fertility improvement, the yield and economic returns from multiple products such as fuelwood and fodder, and the possibility of avoiding the risk associated with monocultural production systems must be carefully weighed against drawbacks.

Key issues concerning alley cropping are its ecological adaptability and labor demand. The provision of nutrients through decomposing mulch, a basic feature of alley cropping, depends on the quantity of the mulch as well as on its quality and time of application. If the ecological conditions do not favor the production of sufficient quantities of mulch (as is the case in dry tropics), there is no perceptible advantage in practicing alley cropping (Rao *et al.*, 1998). The issue of high labor demand is associated with the pruning of the shrubs and the incorporation of the biomass in the field. There are also some issues of pest management problems of mixed species stands as well as newly introduced species, and tree–crop competition for growth resources such as nutrients, water, and light. All these issues have contributed to poor rates of farmer adoption of the alley-cropping technology.

Another agroforestry technology that has been promoted, especially in nutrient-depleted African soils, is improved fallow with 'fertilizer trees.' Basically, one or a few (mixed) tree species, usually biological nitrogen fixers, are planted at high density as a substitute to natural fallow, to achieve the benefits of the latter in a shorter time of 2–3 years versus 15–20 years of natural fallow (Buresh and Cooper, 1999). The production of biomass in planted fallows as well as the potential of planted fallows to ameliorate soil fertility is controlled by several factors: environmental conditions, soil type,

land degradation, length of the fallow period, density of tree planting, tree management, and soil and climatic conditions. Improved fallows are reported to sequester substantial amounts of C in plants and soil in the short term (Sanchez, 1999; Albrecht and Kandji, 2003), and enhance the stabilization of water-stable aggregates, which in turn decreases the risk of erosion in subsequent crop periods, thus contributing to the sustainability of the system (Mutuo, 2005).

In the temperate region as well as Australia, alley cropping refers to growing herbaceous (agricultural) crops in the alleys between rows of widely planted trees that are planted in single or grouped rows (**Figure 1**). This tree-row and alley arrangement allows the use of farm machinery and equipment and reduces the need for manual labor. Black walnut (*Juglans nigra*), a valuable timber- and nut-producing tree is the species most widely used in alley cropping in North America (**Figure 3**). The common spacing adopted is 12.5 m between tree rows and 3 m between trees within a row (270 trees ha^{-1}). The driving force behind most temperate-zone alley cropping is economic benefits from the intercrop. Soil conservation in gently sloping lands could be an additional advantage. Various aspects of this practice have received considerable research attention in the eastern and midwestern USA and Canada (Garrett, 2009). Other similar systems in the temperate regions include the traditional intercropping practice used in the establishment of fruit and nut trees including olive (*Olea* spp.) and grapes (*Vitis* spp.) in Europe, with pecan (*Carya illinoensis*) trees in southeastern USA, and with paulownia (*Paulownia* spp.) trees in China.

The most widespread form of agroforestry, in terms of the area involved, is perhaps the extensive intercropping under-scattered stand of trees, particularly in the semiarid regions of sub-Saharan Africa and Asia. The so-called parkland system of sub-Saharan Africa (**Figure 4**) extends across the entire semiarid belt from Senegal in the west to Ethiopia and Kenya in the east (Boffa, 1999). It originated from the practice of the traditional shifting cultivation in which farmers conserved in their fields the trees that are desirable for shade, fodder, fruits, and medicines. The trees that are most common include *Faidherbia albida*, *Parkia biglobosa*, and *Vitelleria paradoxa*. The understory species include both crops (millet, cassava, cotton, maize, and others depending on climatic and soil conditions) as well as grasses for animal grazing, where animals are let loose for grazing over crop residues and grasses. The practice is therefore considered as extensive intercropping or silvopasture.

Multistrata Systems

Intensive, multispecies, tree-based farming systems such as homegardens, shaded perennial stands, and other complex agroforests are common agroforestry practices in the humid and subhumid parts of the tropics, especially in the lowlands (**Figure 5**). The structural and functional diversity and various other characteristics of these systems have been well described and reviewed (Nair, 1989; Kumar and Nair, 2006). Homegardens have a long tradition of providing food and nutritional security as well as environmental sustainability in smallholder production systems, often in heavily populated regions of lowland humid tropics in south- and southeast Asia, and to a small extent in other tropical and subtropical regions. Although a few systems that have some similarities to tropical homegardens can be found in parts of the temperate regions as well (e.g., the satoyama system in Japan: Ichikawa and Toth, 2012), intensive multispecies homegardens are a unique agroecosystem of the tropics.

Shaded-perennial systems that involve growing tree crops such as coffee (*Coffea* sp.) and cacao (*T. cacao*) under the shade of overstory tree species (**Figure 6**) represent another traditional example of high-intensity crop combination that has some unique ecological features and commercial value. In addition to coffee and cacao, several of the tropical fruit- and nut-producing tree species that are harvested annually or at shorter intervals are often grown in association with understory- or overstory species (Elevitch, 2006, 2011; Gama-Rodrigues *et al.*, 2010). In some situations, the species combinations and management features of these systems are very similar to those of homegardens such that, at the landscape- and village level, there is a continuum of plant associations from

Figure 4 Parkland system. A mature stand of maize (*Zea mays*) under a sparse stand of *Faidherbia albida* trees in Malawi. Reproduced from Ajayi, O.C., Place, F., 2012. Policy support for large-scale adoption of agroforestry practices: Experience from Africa and Asia. In: Nair, P.K.R., Garrity, D.P. (Eds.), Agroforestry: The Future of Global Land Use. Dordrecht, The Netherlands: Springer, pp. 175–201.

Figure 5 Homegarden. Homegardens that consist of intimate, multistory combinations of various trees and crops around homesteads provide food- and cash security as well as social and esthetic benefits to millions of farm households around the tropics. The picture shows a homegarden with coconut palms (*Cocos nucifera*); various fruit- and nut-producing trees such as jackfruit tree (*Artocarpus* sp.), mango (*Mangifera indica*), and nutmeg (*Myristica fragrens*); and food crops such as plantains (*Musa* spp.), cassava (*Manihot esculenta*), and rice (*Oryza sativa*) in the foreground, in a Kerala homegarden, southwestern India.

Figure 6 Shaded perennial system. Shaded perennial-crop systems involve growing shade-tolerant commercial species such as coffee (*Coffea* sp.) and cacao (*Theobroma cacao*) under overstory shade trees. The photo shows a coffee field with Erythrina poeppigiana as the shade tree in Costa Rica. Photo: E. Somarriba, CATIE, Costa Rica.

homegardens nearer homes to multistrata tree gardens away from the homes.

Characterized as the epitome of sustainability, these multispecies tree–crop combinations are excellent examples of efficient land-management systems by smallholder farmers. With heavy reliance on human (often family) labor for the farm operations, conventional tillage operations involving machinery are minimal or absent in such systems. Some of the distinguishing ecosystem sustainability features of these systems include efficient and 'closed' nutrient cycling facilitated by continuous litter fall and decomposition and very little export of nutrients from the system by way of harvested products, the reliance on organic manure and plant materials with consequent avoidance of chemical-fertilizer use, and predominance of deep-rooted trees, which collectively contribute to the high levels of C sequestration and climate-change mitigation in these systems, as evidenced by the recent studies by Saha *et al.* (2010) in the homegardens of Kerala, India, and Gama-Rodrigues *et al.* (2010) in the shaded cacao systems of Bahia, Brazil.

Protective AFS

These systems encompass the use of trees and shrubs for exploiting their ecosystem-protection benefits by planting them as windbreaks, riparian buffers, soil conservation hedges, and similar other configurations. Windbreak practices include shelterbelts, timber belts, and hedgerows, and are planted and managed as part of a crop or livestock operation. Field windbreaks are used to protect a variety of wind-sensitive row, forage, tree, and vine crops, to control wind erosion, and to provide other benefits such as improved bee pollination of crops and wildlife habitat (Brandle *et al.*, 2009). For livestock, windbreaks help reduce animal stress and mortality, feed and water consumption, and odor, whereas timber belts are managed windbreaks designed to increase the value of the forestry component. Shelterbelts are also planted along the coastal areas to reduce the impact of sea encroachment and protect crops from salt-water damage. Riparian and 'upland' buffers are strips of permanent vegetation, consisting of trees, shrubs, and grasses that are planted and managed together. Riparian buffers are placed between agricultural land (usually crop land or pasture land) and water bodies (rivers, streams, creeks, lakes, wetlands, etc.) to reduce runoff and nonpoint source pollution, stabilize stream banks, improve aquatic and terrestrial habitats, and provide harvestable products (**Figure 7**). Upland buffers are placed along the contour within agricultural crop lands to reduce runoff and nonpoint source pollution, improve internal drainage, enhance infiltration, create wildlife habitat and connective travel corridors, and provide harvestable products (Schultz *et al.*, 2009). As discussed under alley cropping, frequently pruned rows of trees and shrubs planted across the contour in crop production fields help reduce soil erosion and the pruned biomass serves as a source of nutrient to crops or can be transported away to be used as animal fodder.

Riparian buffers are a common feature of the landscape in the US north central region in particular (Jose *et al.*, 2012), as well as in Canada (Thevathasan *et al.*, 2012). In addition to the benefit of C sequestration, these protective systems can provide additional C benefits due to improved crop and livestock production and energy savings (Kort and Turnock, 1999). Recognizing that agricultural runoff as a key contributor to nonpoint source pollution (NPSP) of water including hypoxia in the Gulf of Mexico, riparian buffer strips are a heavily subsidized agroforestry practice by US Federal cost-share programs such as the Conservation Reserve Program, Environmental Quality Incentives Program, Forest Stewardship Program, Wetlands Reserve Program, and Wildlife Habitat Incentives Program (Jose *et al.*, 2012).

Figure 7 Riparian buffer. Bear Creek National Restoration Watershed (designated under the Clean Water Action Plan, 1999) and the USDA designated Bear Creek National Research and Demonstration Site. Figure 8 Silvopasture. Beef cattle grazing on *Brachiaria brizantha* (grass) grown under *Eucalyptus* hybrid trees on a farm in Minas Gerais, Brazil.

Silvopasture

Silvopasture that combines trees, forages, and shrubs with livestock operations is another type of agroforestry practice that is popular in both the tropics and the temperate regions. Broadly, there are two major forms of silvopasture: grazing- and tree-fodder systems. In grazing systems, cattle are allowed to graze on pasture under widely spaced or scattered trees (**Figure 8**), whereas in the tree-fodder systems, the animals are stall-fed with fodder from trees or shrubs grown in blocks (fodder banks) on farms (Nair *et al.*, 2008; Kiptot and Franzel, 2012). Most silvopastoral systems in Africa and other developing regions of the world involve extensive open grazing by free-roaming animals under scattered natural stands of trees and shrubs mostly in semiarid to arid areas, as in the parklands of sub-Saharan Africa. More intensive grazing systems of silvopasture are practiced in Latin America where animals are penned in parcels of land with barbed-wired living-fence, and grazing is regulated (Somarriba *et al.*, 2012). Such 'organized' silvopastoral systems are also becoming popular in the extensive Cerrado region of Brazil (Nair *et al.*, 2011). The most intensive silvopastoral system is the stall feeding of animals by fodder from trees grown elsewhere, which is a very common practice in smallholder farming systems as described by Kiptot and Franzel (2012). The grazing system of silvopasture has recently gained prominence as an environmentally desirable approach to managing degraded pasture lands in the industrialized countries (Rigueiro-Rodriguez *et al.*, 2008; Garrett, 2009).

Silvopasture embodies the goals of desirable management practices for climate-change mitigation (especially in terms of grazing and manure addition) and C sequestration.

Additional benefits of silvopasture include water quality improvement (Michel *et al.*, 2007), soil conservation, esthetics, and providing shade to cattle (Garrett, 2009). Alternative land uses including sustainable forest management, outdoor recreation, and ecotourism, and most encouragingly silvopasture, are considered highly compatible with traditional ranching and include several elements of best management practices for ranchers (Garrett, 2009).

Tree Woodlots and Specialty Crops

These terms are used to denote agroforestry practices that are undertaken for special situations and needs. Examples include growing tree woodlots as fodder banks (for production of cut-and-carry tree-fodder), boundary planting of trees for production of firewood, small timber, poles and fence posts; tree planting for reclamation of degraded lands such as saline soils and mined land (Quinkenstein *et al.*, 2012); establishing tree woodlots for biomass and bioenergy production such as in the Canadian prairies (Kort and Turnock, 1999; Thevathasan *et al.*, 2012) growing specialty products such as ornamentals, honey, and high-value crops for niche markets; and a whole host of such 'nonconventional' land-use systems. The extent of people and areas involved and the economic benefits derived from such activities are seldom documented. Among these activities only large-scale tree woodlots would count as major activities in terms of carbon sequestration and climate change mitigation, although all would be important for their economic, social, and cultural benefits.

Figure 9 Fallow regeneration. Farmer-managed natural regeneration of fallow in Burkina Faso. Reproduced from ICRAF.

One of the best ways of reclaiming areas degraded by severe soil erosion, acidity, salinity or alkalinity, and other forms of land degradation is by planting tree species that are adapted to such conditions and leaving the land under the tree woodlot for several years (20 or more, depending on local conditions) before it is opened up for planting crops or fodder grasses. Several such programs, under the banner 'wasteland development,' supported by various government agencies and with the involvement of nongovernmental organizations and local communities are popular in India. Another example of large-scale implementation of protective agroforestry is the 'fallow regeneration' that is gaining momentum in different parts of arid and semiarid sub-Saharan Africa (**Figure 9**). For example, the recent rejuvenation of the centuries-old parkland AFS of the Sahel through the spread of farmer-managed natural regeneration has been documented to have occurred on nearly 5 million hectares by 2008 in Niger alone (Reij *et al.*, 2009; Garrity, 2012).

Role of Agroforestry in Land Management in the Twenty-first Century

Agroforestry began to attract the attention of the international development and scientific community in the 1980s as a means for increasing and sustaining agricultural production in marginal lands and remote areas of the tropics that were not benefited by the Green Revolution. Thanks to the research and development efforts at various local, regional, and global levels, agroforestry is at present recognized as having the potential to offer much toward sustainable land management and environmental integrity in poor and rich nations alike. Discussing the role of agroforestry in land management in the twenty-first century, Nair and Garrity (2012) identified food security, climate change mitigation and adaptation, and other ecosystem services as the key areas where the impact of AFS could be conspicuous in the immediate future.

Food Security

In sub-Saharan Africa, which is home to three-quarters of the world's 'ultra-poor' (less than US$0.50 per day), approximately 218 million people, roughly 30% of the continent's total population, struggle with hunger daily (United Nations, 2010). Soil-fertility depletion, exacerbated by continuous cropping without nutrient inputs in the inherently poor soils, is a major challenge in the dryland ecosystems that dominate these regions. Reversing this trend and restoring soil health in the smallholder African farming systems has become a major development policy issue on the continent. The most urgent need is to increase biomass production in the farming system with richer sources of organic nutrients to complement whatever amounts of inorganic fertilizers that a smallholder farmer can afford to apply. The integration of 'fertilizer trees' such as *Calliandra*, *Gliricidia*, *Sesbania*, and *Tephrosia* as improved fallows into food crop agriculture is a promising, but underappreciated, approach to accomplishing this.

Recent advances in agroforestry based on the use of fertilizer trees and other trees have produced a range of promising approaches to accomplishing this through a portfolio of options, now referred to as Evergreen Agriculture (Swaminathan, 2012). Evergreen Agriculture emphasizes the application of sound, tree-based management practices, and the knowledge to adapt these to local conditions, to optimize fertilizer and organic resource-use efficiency for greater crop productivity. It is also compatible with reduced tillage, increased residue retention on the soil surface, and other principles of conservation agriculture, in situations where these practices are feasible and appropriate. Currently, *F. albida* is showing promise as a cornerstone of Evergreen Agriculture for fallow regeneration and restoration of soil fertility in dry areas (Garrity, 2012).

The important role of fruit- and other food-producing trees in providing food security especially to low-income households is another important issue to be considered in this context. A large number of such trees grown in intimate association with herbaceous crops in homegardens and intercropping systems (Elevitch, 2006; Kumar and Nair, 2006, Leakey, 2012b) provide food security as well as nutritional security to millions of households throughout the tropics. Scientific efforts to domesticate and improve traditionally important, but underutilized, trees as a means to intensifying AFS are currently receiving deserved research attention in agroforestry (Leakey *et al.*, 2012). Domestication and improvement of the multitude of such indigenous agroforestry trees offer enormous opportunities to enhance food- and nutritional security as well as generating household income, especially in the tropical and subtropical developing regions.

Pathways to increasing food security also include the ability to increase livestock production in integrated crop-livestock-tree systems, which are dependent on greater sustainable sources of high-quality fodder (Herrero *et al.*, 2010). The impact of fodder tree production and income among smallholder dairy farmers in East Africa has emerged as a major area of agroforestry impact (Kiptot and Franzel, 2012). Additional pathways to smallholder food security are also achieved through the production of higher-value products that are sold for increased income, and the husbandry of tree crops, such as timber, also increases the farm asset base (Garrity, 2004). The integration of trees into crop- and livestock-production systems opens up opportunities for all these pathways on the small-scale farm.

Table 3 Estimates of carbon sequestration in agroforestry systems in different ecological regions of Africa and Asia

Agroforestry system subgroup	*Major AF practices*	*Estimated C stock range (Mg ha^{-1})*		*C Seq Potential (CSP) in new areas (Mg ha^{-1} yr^{-1})*	
		Above ground	*Below ground (especially soils)*	*Above ground*	*Below ground (soils)*
Multistrata systems	Homegardens	2 to 18	Up to 200	0.5–3	1.5–3.5
	Shaded perennials	5 to 15	Up to 300	1–4	1.0–5
Tree Intercropping	Alley cropping	Up to 15	Very low to 150	0.5–4	1.5–3.5
	Multipurpose trees on farmlands	Up to 12	Very low to 150	0.2–2.5	1.5–3.5
Silvopasture	Tree fodder (browsing, cut-and-carry)	1.8–3	Very low to 80	0.3–4	1.0–2.5
	Grazing under trees	1.5–8	Very low to 60	0.3–2	0.4–1.0
Protective systems	Windbreaks, shelterbelts, soil conservation hedges, boundary planting	1.5–7	Very low to 60	0.7–2	0.4–1.0
Agroforestry Tree woodlots	Woodlots for firewood, fodder, land reclamation	1.5–7	Very low to 60	1–5	1.0–6.0

Climate Change Adaptation and Mitigation

Agroforestry is a key approach to the integration of climate change adaptation and mitigation objectives, often generating significant cobenefits for local ecosystems and biodiversity (Matocha *et al.*, 2012). Synergies between climate change adaptation and mitigation actions are particularly likely in situations involving income diversification with tree and forest products. These options also reduce the susceptibility of land use systems to extreme weather events, enhance soil fertility, and favor the conservation and restoration of forest and riparian corridors. Evaluating the role of agroforestry in climate change adaptation and mitigation, Nair (2012a) concluded that whereas existing multistrata and tree intercropping systems will continue to provide substantial climate change mitigation benefits, large-scale initiatives in grazing land management, working trees in drylands, and the establishment of vegetative riparian buffer and tree woodlots are the most promising agroforestry pathways for both adaptation and mitigation.

Sequestration of carbon in soils and in the biota, along with payments to resource-poor farmers for the ecosystem services rendered, would be a timely win-win strategy in the fight against food-insecurity and global warming (Lal, 2010). The role of agroforestry in carbon sequestration is now well articulated (Nair *et al.*, 2010) for many AFS (**Table 3**). Consequently, there is considerable interest in the creation of biocarbon investment funds to channel carbon offset payments from developed countries to stimulate more carbon sequestration while simultaneously enhancing the livelihoods of smallholders and the environment. These investments will encourage development pathways resulting in higher landscape-level carbon stocks (Garrity *et al.*, 2010).

Ecosystem Services

Exploiting nitrogen fixation by tropical legumes, enhancing the efficiency of nutrient cycling, and benefitting from the deep-capture of nutrients are recognized as the primary bases of the soil sustainability advantages of such systems. The focus of soil-improving qualities of multipurpose trees that dominated agroforestry research agenda during the 1980s and 1990s was on realizing these benefits at the farm or local level. Since the 1990s, other ecosystem services of trees that transcend from local to global levels such as climate change mitigation through carbon sequestration and biodiversity conservation have received increasing attention. The biodiversity conservation attributes of agroforestry stem from the species diversity and complexity of such systems. The trend toward major public investments for rewarding farmers for the ecosystem services their enterprises provide to society, in both the developed world and the emerging economies such as China and India, suggests that the integration of trees into agricultural systems will be a major opportunity in the succeeding decades.

Conclusions

Modern agricultural systems have resulted in significant gains in agricultural production worldwide and averted large-scale hunger over the past half century. Yet, many developing regions of the world, notably sub-Saharan Africa, lag behind the rest of the world in food production and other aspects of development. This is because the input-intensive agricultural technologies of the Green Revolution have turned out to be unsuitable for Africa's infertile soils, unforgiving climate, weak infrastructure, and sociocultural traditions. During the past 35 years, research and development efforts have widely demonstrated the positive role of AFS in addressing some of the major problems of Africa and other parts of the world such as food- and nutritional insecurity, soil degradation, desertification, and climate change; yet agricultural development efforts have vastly ignored the values of such time-tested integrated systems and their social values.

Conventionally, one has treated agriculture and forestry separately although these sectors are often interwoven on the

landscape and share many common goals. These disconnects are one of the main causes of failure of land-use systems to meet the needs of the people in ways that confer sustainability. Agroforestry offers the opportunity to exploit the potential of the multitude of indigenous plants that provide multiple products and ecosystem services and incorporate them into widely adoptable land-use systems to improve the lives of millions of people and our environment.

Glossary

Air Pollutant Foreign and/or natural substances occurring in the atmosphere that may result in adverse effects to humans, animals, and/or the surrounding environment.

Ammonia (NH_3) A colorless gaseous compound of nitrogen and hydrogen that is highly soluble in water and has the ability to react with oxides of nitrogen to form ammonium nitrate, a particulate matter that contributes to air pollution and the resulting health implications.

Anaerobic digestion A biochemical process in which bacteria break down biodegradable organic material, such as manure, in an oxygen-free environment. The breakdown of organic materials results in the production of biogas, typically a mixture of methane and carbon dioxide.

Anthropogenic Originating from human activity.

Confined Animal Feeding Operation (CAFO) Agricultural operations where animals are kept and raised in confined areas, where animals feed, manure, and production operations are on a small land area. Usually, feed is brought to animals in CAFOs rather than the animals grazing. The US Environmental Protection Agency (EPA) separates CAFOs into three categories (large, medium, and small) based on the number of animals in a facility.

Criteria pollutant Six emissions identified and regulated by the EPA, including: sulfur dioxide, nitrogen dioxide, particulate matter, carbon monoxide, ozone, and lead.

Enteric fermentation The digestive process in ruminant animals, such as beef and dairy cattle, sheep, and goats, by which feed is broken down by microorganisms (bacteria, protozoa, and archaea) into simple molecules for absorption into the bloodstream. Byproducts of enteric fermentation include gaseous compounds (methane, carbon dioxide, etc.), which are expelled from animals via eructation.

Odors A substance giving off a smell, caused by one or more volatilized chemical compounds. In animal production, odorants are a major concern for the general public, as urban encroachment of agricultural land increases.

Particulate matter (PM) Any material that exists in the solid or liquid state in the atmosphere. The size of PM can vary from coarse, windblown dust particles to fine particles. Coarse particles (PM_{10}) range between 2.5 and 10 μm in diameter. Fine particles ($PM_{2.5}$) are less than 2.5 μm in diameter. Both PM_{10} and $PM_{2.5}$ can affect human and animal health and can contribute to smog and ozone formation.

Volatile organic compounds (VOCs) Carbon-containing compounds that evaporate into the air. These compounds contribute to the formation of smog and odor.

Introduction

The world population is expected to grow from today's 7 billion people to 9.3 billion people by 2050 (United Nations, 2009). Although the human population shows this dramatic growth, the amount of arable agricultural land needed to grow food to nourish these people is limited and can only increase moderately. Furthermore, increasing disposable income in developing and emerging countries leads to higher per capita consumption of animal protein, leading to an expected increase in global dairy and meat consumption of 74% and 58%, respectively (UNFAO, 2012). Thus, food production must become more efficient and intensification is one of the most viable solutions. In general, concentrated animal feeding operations (CAFOs) allow the production of relatively low cost food; however, there are externalities associated with CAFOs, such as air and water pollutants, and greenhouse gas (GHG) emissions.

Over the past decades, there has been a shift from traditional, rather low input, and extensive farms to CAFOs in the US and throughout much of the developed world. Owing to the increase in the number of CAFOs and the air quality issues surrounding them, the US Environmental Protection Agency (EPA) has created nationwide specifications for what constitutes a CAFO as well as what emissions from these operations must be monitored and mitigated.

For an animal operation to be considered a CAFO, it must first meet the definition of an animal feeding operation (AFO). An AFO is an 'operation where animals have been, are, or will be stabled or confined and fed or maintained for a total of 45 days or more in any 12-month period and where vegetation is not sustained in the confinement area during the normal growing season' (USEPA, 2012b). 'Maintained' in this case means that the animals are confined in the same area where waste is generated or concentrated and can include areas where animals are fed, watered, cleaned, groomed, milked, or medicated (USEPA, 2012b). This definition also distinguishes AFOs from pasture- or grazing-based systems; therefore, animals raised on pasture are not considered to be produced in an AFO.

AFOs are defined as either medium- or large-sized CAFOs if a series of EPA specifications apply. Most significantly, an AFO is considered a CAFO if it is determined to be 'a significant contributor of pollutants to waters of the US' (USEPA, 2012b). Dairy and beef cattle, veal calves, swine, chickens, turkeys, ducks, horses, and sheep can all fall within the CAFO designation if specific threshold numbers are met. This article presents three types of CAFOs, namely those for large ruminants (beef and dairy cattle), swine, and poultry (broiler and layer).

Among the benefits of CAFOs are that they show decreases in animal mortality rates, improved feed efficiencies, and improved productivity (ASABE, 2006). However, CAFOs also have externalities including the production and emissions of nuisances, air pollutants, and GHGs. Emissions from CAFOs that contribute to poor air quality can vary in severity between the types of animals being produced (NRC, 2003); however, the key issues related to air quality remain the same across livestock production systems. Air emissions associated with CAFOs can include odorous, gaseous, and particulate compounds. This article will highlight the major air quality issues associated with CAFOs.

Air Pollutants

Air pollutants affect human and animal health as well as ecosystem health and visibility (Pope *et al.*, 2009; Cambra-Lopez *et al.*, 2010). Criteria pollutants that are regulated in the US and that have the greatest effects on air quality include carbon monoxide (CO), lead (Pb), nitrogen dioxide (NO_2), particulate matter (PM) of less than 10 μm in diameter (PM_{10}), PM of less than 2.5 μm in diameter ($PM_{2.5}$), ground level ozone (O_3), and sulfur dioxide (USEPA, 2001). These criteria pollutants and some of their precursor compounds are regulated under the Clean Air Act and enforced by the USEPA, to address direct public health concerns (USEPA, 2012a). The National Research Council (NRC, 2003) provided a list of air emissions, which contribute most significantly to air quality concerns (**Tables 1** and **2**). In CAFOs, the primary air pollutants of concern are PM, ammonia (NH_3), hydrogen sulfide (H_2S), volatile organic compounds (VOC), and odors. Although NH_3, H_2S, VOCs, and odors are not directly regulated from most environmental agencies (with the exception of central and southern California), it is important to minimize these emissions because they can lead to the formation of criteria pollutants and often constitute nuisances. For example, ammonia can contribute to secondary PM formation (Pinder *et al.*, 2007), VOCs can contribute to O_3 formation (Shaw *et al.*, 2007; Sun *et al.*, 2008), and both NH_3 and VOCs contribute to odor production, a growing concern for policymakers as well as the general public. Additionally, there is an association between exposure to PM and adverse human and animal health effects in livestock CAFOs (Aneja *et al.*, 2009). Human exposures to $PM_{2.5}$ have been associated with pulmonary disease (Pope *et al.*, 2009) and those to PM_{10} with decreased lung function, cardiac arrhythmia, heart attacks, and premature death (Madden *et al.*, 2008). PM also contributes to impaired atmospheric visibility by scattering and absorbing light (Boylan *et al.*, 2006), issues which are discussed in other article.

The following section discusses air quality issues emitted across all CAFO types.

Ammonia

Livestock is estimated to be the single largest source of NH_3 emissions in the US, producing 71.3% of annual emissions (USEPA, 2000). Ammonia primarily results from manure degradation and forms when urease, an enzyme present in animal feces, catalyzes the hydrolysis of urea from urine (Sun *et al.*, 2008). The formation of ammonia occurs as follows:

$$(NH_2)\bullet 2CO + H_2O \rightarrow CO_2 + 2NH_3$$

Ammonia emissions are dependent on the amount of urea nitrogen (urea-N) and degree of mixing between urine and feces (Bussink and Oenema, 1998) and as a result, there are great variations in NH_3 emissions between farms (James *et al.*, 1999; VandeHaar and St-Pierre, 2006), manure land-application methods (Amon *et al.*, 2006), and time of year (Bussink and Oenema, 1998). The production rate of urea-N, and subsequently NH_3, is directly related to the concentration of nitrogen ingested by animals. Urea in ruminants is produced in the liver (detoxification of ammonia from blood circulation) and excreted in the urine. Overfeeding protein in the diet commonly leads to increased urea excretions, which affects NH_3 formation (Burgos *et al.*, 2010). The volatilization of NH_3 from any CAFO can be highly variable depending on the total NH_3 concentration in the solid or liquid phase, temperature, pH, and manure storage time. Emissions depend on how much of the N in solution reacts to form NH_3 versus ionized ammonium ($NH4^+$), which is nonvolatile (i.e., a nongaseous compound) (USEPA, 2001).

In general, NH_3 loss to the atmosphere can lead to PM formation, soil acidification, and eutrophication of surface waters (Fangmeier *et al.*, 1994; Krupa, 2003; CAST, 2011) and decreased livestock performance (Drummond *et al.*, 1980).

Table 1 Ranking of the importance of Animal Feed Operation (AFO) emissions at global and local scales

Emissions	*Global, national, and regional*	*Local, property line, and nearest dwelling*	*Primary effects of concern*
Methane (CH_4)	Significant[a]	Insignificant	Global climate change
Nitrous oxide (N_2O)	Significant	Insignificant	Global climate change
Ammonia (NH_3)	Major	Minor	Atmospheric deposition
Volatile organic compounds(VOCs)[b]	Insignificant	Minor	Quality of human life
Particulate matter	Insignificant	Significant	Health, haze
Odor	Insignificant	Major	Quality of life

[a]Ranking of the importance of each emissions based on NRC recommendations for the potential impact of emissions, both locally and nationally. Rank order from high to low is as follows: major, significant, minor, and insignificant.

[b]According to the NRC, 2003, compared with other sources, VOC emissions from AFOs are considered to be insignificant; however, recent research may warrant changes in this classification.

Hydrogen Sulfide

Hydrogen sulfide (H_2S) and other reduced sulfur compounds are produced as manure decomposes anaerobically, resulting in the breakdown of organic matter. Hydrogen sulfide can arise from storage, handling, and decomposition of animal waste. There are two primary sources of sulfur in animal manures: (1) the sulfur amino acids present in animal feed and (2) inorganic sulfur compounds, such as copper sulfate and zinc sulfate, which are used as feed additives to supply animals with trace minerals and serve as growth stimulants for animals (USEPA, 2001; NRC, 2003). Although sulfates are used as trace mineral carriers in all sectors of animal agriculture, their use is more extensive in the poultry and swine industries. A possible third source of sulfur in some locations is trace minerals in drinking water (USEPA, 2001; NRC, 2003). Under anaerobic conditions, any excreted sulfur that is not in the form of H_2S will be reduced microbially to H_2S. Therefore, manure managed in liquid form or slurries are potential sources of H_2S emissions. The magnitude of H_2S emissions is a function of liquid phase concentration, temperature, and pH. Temperature and pH affect the solubility of H_2S in water. The solubility of H_2S in water increases at pH values above 7. Therefore, as pH shifts from alkaline to acidic, the potential for H_2S emissions increases (Snoeyink and Jenkins, 1980; USEPA, 2001). Under anaerobic conditions, livestock and poultry manures are acidic, with pH values below 5.5 (USEPA, 2001). In addition, H_2S causes respiratory problems (Donham *et al.*, 1986) and may lead to adverse effects on workers' health (Mitloehner and Calvo, 2008). Hydrogen sulfide is toxic and can be highly dangerous especially when it is suddenly released in high concentrations from stored manure in a confined area and has caused human and animal mortalities (Ni *et al.*, 2012).

Volatile Organic Compounds

VOCs vary in their reactivity and contribution to O_3 formation (Carter, 1994), and many of the VOCs emitted from fermented animal feeds have low ozone-formation potentials relative to other anthropogenic sources (Howard *et al.*, 2010a,b); however, the quantity of VOC emissions produced from CAFO feed (dairy facilities in particular) generates a valid air quality concern. VOCs are formed as intermediate metabolites in the degradation of organic matter in feed and manure (USEPA, 2001). Under aerobic conditions, any VOC formed is rapidly oxidized to carbon dioxide and water. Under anaerobic conditions, complex organic compounds are degraded microbially to volatile organic acids and other VOCs, which in turn are converted into methane and carbon dioxide by methanogenic bacteria (USEPA, 2001). When the activity of the methanogenic bacteria is optimal, virtually all of the VOCs are metabolized to simpler compounds, such as CH_4, and the potential for VOC emissions is minimal (USEPA, 2001). Other effects of VOC emissions include odor production, PM formation, O_3 formation, and ecosystem degradation (Cambra-Lopez *et al.*, 2010; Pinder *et al.*, 2007). Additionally, VOC emissions can lead to adverse health effects, such as ear, nose, and throat damage (Mitloehner and Calvo, 2008). VOCs encompass a wide range of compounds.

Odors

Odors from CAFOs are a major nuisance and have the potential to negatively impact the quality of life for the nearby residents (Fournel *et al.*, 2012). Gaseous compounds associated with odor vary greatly in molecular weight and odorant strength making it challenging to quantify and compare odors. As a result, the concept of an 'odor unit' (OU) was developed as a way to normalize the specific odor-related effect of an odor or mixture of odors. There are six major groups of odorous compounds, as identified by Mackie *et al.* (1998), which includes the previously discussed air pollutants, NH_3 and VOCs, and several sulfur-containing compounds.

Large Ruminant Facilities

Large ruminant facilities include both dairy and beef cattle operations. In 2009, US dairy and beef industries produced 85.9 billion kilogram of milk and 11.8 billion kilogram of beef, respectively (USDA, 2010). Both the industries span the continental US and range from small- to large-scale operations. Although there are still extensive, pasture-based dairy and beef operations in the US and around the world, this article focuses on intensive dairy and beef CAFOs. Typically, dairy CAFOs are integrated, freestall operations, whereas beef CAFOs are feedlots. This section provides a brief description of both dairy and beef CAFOs and the air quality issues surrounding these facilities.

Most freestall dairies are integrated, which means that they house calves, growing heifers, and dry and lactating cows on the same farm. Animals in dairy CAFOs are typically housed and fed in confinement and manure is removed from housing areas daily. Most feedstuffs are piled up on the farm premises and mixed to assemble a total mixed ration (TMR) for the

cows. On dairy CAFOs, calves are typically fed milk or milk replacer, and diets are supplemented with grain. Calves are housed individually in calf hutches for approximately 2 months, until animals are weaned. Heifers are group housed and fed a forage-based TMR, and are managed to calve at approximately 2 years of age. Dry cows are fed a high-forage TMR for a 60-day period between lactations in order to recover before the next lactation. Finally, lactating cows are fed a high-nutrient, well-balanced TMR to optimize milk production.

The most intensive sector in beef cattle production is the finishing phase. This is the final phase of beef production and involves housing cattle in dirt-floored drylot corrals known as feedlots. The time an individual steer or heifer spends in a feedlot depends on its entering weight, rate of gain, and desired weight at slaughter. Cattle typically enter feedlots at 350–400 kg, with the exception of male dairy calves, which enter at 150 kg (Stackhouse *et al.*, 2011). On average, cattle are housed for a total of 4–6 months until a slaughter weight of approximately 550 kg is reached (Stackhouse *et al.*, 2011). Feedlot cattle are fed a high-concentrate diet containing 75–90% corn, soybean meal, dried distiller's grains, etc. and 10–25% roughage.

Manure management in large ruminant CAFOs is critical due to the sheer size of these animals and associated amounts of excreta. An adult bovine excretes 41–60 kg of feces and urine daily (Davis *et al.*, 2002; CAST, 2011). Typical manure management in dairy CAFOs involves scraping excreta from dirt-floored corrals and piling it into dry storage piles. Manure from concrete floored freestall barns in which mainly lactating cows are housed can occur by either scraping or flushing. Most modern dairies prefer the latter and manure is flushed into liquid storage structures, which are often referred to as lagoons. If managed inappropriately (e.g., by overloading with nutrients), lagoons can be major sources of NH_3, H_2S, and odor emissions. In addition, manure lagoons are large contributors of GHG emissions in dairy CAFOs. Although land-application practices of dairy manure can vary, most large dairies use flood irrigation of liquid manure from the lagoons to fertilize crops on the surrounding fields. In beef CAFOs, manure from a corral is typically removed every 4–6 months, namely after a cattle group is leaving to be slaughtered. During the time cattle reside in the corrals a manure pack is formed, which can be a source of odor and PM emissions. Scraped manure from cattle corrals are mostly land applied to crops as fertilizer. Management of manure in dairy CAFOs can affect the chemical and physical properties of manure, including chemical composition, microbial populations, oxygen content, pH, biodegradability, and moisture content (MC). Manure storage allows for conservation of nutrients present in manure, which can then be utilized for application onto cropland, biodigesters, or composting.

In addition to manure management, there are several other air emission sources that result from beef and dairy CAFOs. Both dairy and beef CAFOs contribute to air pollution through emissions from animals (also known as enteric fermentation), manure, cropping systems, and feed management. This section covers the major air pollutants contributing to air pollution from dairy and beef CAFOs, namely NH_3, H_2S, VOCs, and odors.

Ammonia

The main sources of NH_3 emissions from dairies are fresh manure, long-term manure storage, and land application of manure (Bussink and Oenema, 1998). Similarly, primary emissions from beef CAFOs are from corrals, manure storage, and field-applied manure (Stackhouse-Lawson *et al.*, 2012). Both dairy and beef cattle have the unique ability, being ruminants, to recycle N back to rumen bacteria that would otherwise be excreted as urinary urea-N. Although this physiological process reduces N losses, an excess of dietary crude protein (CP) beyond the animal's nutritional needs leads to an increase in urinary urea-N content (Marini and Van Amburgh, 2005). As mentioned in the Section Air Pollutants, NH_3 emissions can be very variable depending on the climate, time of year, etc. For example, NH_3 emissions from dairies were found to be two to three times greater during the summer compared with winter (Todd *et al.*, 2008; Bluteau *et al.*, 2009). Emissions of NH_3–N from feedlots has been estimated to be as low as 9% and as high as 56% of N fed to animals (Faulkner and Shaw, 2008; Todd *et al.*, 2008; CAST, 2011). Total NH_3 losses at dairy CAFOs can range from 17 to 40 kg N per year per cow (Bussink and Oenema, 1998) or between 20 and 40 g NH_3–per day per AU (animal unit) in freestall areas (Groot Koerkamp *et al.*, 1998; Snell *et al.*, 2003). Diet can be altered to reduce the amount of NH_3 emissions from manure (James *et al.*, 1999; VandeHaar and St-Pierre, 2006). Through optimization of N content of a diet, N excretion per unit of product, and the related NH_3 emissions, can be reduced (de Boer *et al.*, 2011). The use of precision feeding that closely matches the nutritional needs of an animal can help to minimize the emissions from manure (Tylutki *et al.*, 2008). Through precision feeding, producers can avoid the expenses associated with overfeeding animals and minimize nutrient excretion that can lead to emissions. This is especially beneficial when monitoring CP content of the diet because it avoids excess N being converted to urea-N, thus avoiding extra emissions of NH_3 to the environment, as mentioned above.

Manure management in dairy and beef CAFOs can also result in variability of NH_3 emissions. For example, ammonia emissions from scraped or dirt-floored corrals have been found to be three times greater than those from flushed systems (Kroodsma *et al.*, 1993). Additionally, with short-term manure storage, solid manure has been found to have significantly higher NH_3 emission rates than liquid manure; however, long-term storage of manure has a reverse effect (Dewes, 1999). In the case of lagoons, a cover provided by either crust or tarp reduces NH_3 compared with uncovered manure storage structures (Sommer *et al.*, 1993). One method to control emissions from manure is through the use of additives. Manure additives include commercially available products that are intended to reduce ammonia volatilization from manure. The additives are typically mixed with water and poured evenly into the manure slurry but effectiveness is variable (USEPA, 2001).

Hydrogen Sulfide

The most significant source of H_2S in dairy and beef CAFOs is from stored manure. When manure is stored in anaerobic

lagoons (as is the case in many dairies) and undergoes microbial degradation, both NH_3 and H_2S are produced (Xue and Chen, 1999). Hydrogen sulfide is the result of anaerobic decomposition of sulfur-containing amino acids within these lagoons. Hydrogen sulfide emissions also contribute to the formation of odorous pollutants, which is further discussed in the Odor Section below.

Volatile Organic Compounds

Among large ruminant CAFOs, dairies are believed to be one of the largest sources of VOC emissions (Malkina *et al.*, 2011). Emissions of VOCs in dairy CAFOs originate predominantly not only from fermented feedstuff before it is ingested (Howard *et al.*, 2010a), but also by manure and from dairy cattle directly via enteric fermentation (Filipy *et al.*, 2006; Shaw *et al.*, 2007; Alanis *et al.*, 2010). Fluxes of VOCs from cows and waste include methanol, acetone, propanal, dimethylsulfide, and acetic acid (Shaw *et al.*, 2007). Additionally, when assessing manure alone from dairies, the most abundant VOC fluxes were found to be methanol and acetic acid (Hobbs *et al.*, 2004; Shaw *et al.*, 2007). Fermented feeds, such as silage, are major sources of VOC and they require large amounts of fossil fuel inputs for production (de Boer, 2003; Schils *et al.*, 2007).

Silage production has recently been identified as a major source of VOCs from dairies (Alanis *et al.*, 2008) and might show to be the leading agricultural source in locations like Central California (Howard *et al.*, 2010a). In a recent study, Chung *et al.* (2010) identified 48 VOCs from dairy sources, which included sources from silage and TMRs, whereas Malkina *et al.* (2011) identified 24 VOCs from silage and TMR emissions.

Odor

According to the National Research Council (2003) the main sources of odors emitted from dairy CAFOs result from silage mounds, barns, waste storage facilities, or land-applied manure. The greatest contributors of odors in livestock CAFOs are several groups of VOCs, including sulfur-containing compounds (hydrogen sulfide), volatile fatty acids (VFAs), phenols, and indoles (Shabtay *et al.*, 2009). Odor emissions from beef cattle fattening operations are affected by life stage and manure management (Shabtay *et al.*, 2009). In dairies, VOCs have the greatest impact on odors. Additionally, land application of manure, storage of manure, and dairy housing have been found to produce odor emissions of 1.5–90, 5.1–32, and 1.3–3.0 OU s^{-1} m^{-2}, respectively (Pain *et al.*, 1991; ASABE, 2006). Techniques to minimize odor from manure storage include covering lagoons, either with a natural crust or an artificial membrane, aerating storage basins (Westerman *et al.*, 2000), or utilizing anaerobic digestion of manure (Powers *et al.*, 1997).

Swine Facilities

To optimize production efficiency, the majority of swine facilities use enclosed and ventilated barns for housing. The hog production cycle has three main phases consisting of farrowing, nursing, and growing/finishing. Swine CAFOs can consist of one or two of these phases per barn but most commonly encompass all three in a farrow-finish production program (USEPA, 2001). In swine CAFOs, emissions are primarily generated from anaerobic microbial decomposition of organic matter in manure and spoiled feedstuff occurring either in barns, manure storage structures, or during manure land application (CAST, 2011). As with other livestock species, swine diet composition has a significant impact on the concentration and type of emissions coming from animal manure. There are various management methods utilized in swine production settings. In the US, swine are mainly intensively managed indoors on bedded or slatted floors. Bedding, such as straw, cornstalks, or sawdust, is used to collect solid manure and this bedding along with the manure is applied to cropland as fertilizer. There are four principal types of waste management systems used with confinement housing in the swine industry: deep-pit, pull-plug pit, pit recharge, and flush systems (**Table 3**). These differ depending on the state of manure collection and frequency of cleaning and draining. All of these systems use slatted floors (USEPA, 2001). The pit system allows the animal waste to fall through the slats directly into a pit and is collected in liquid form (Hamon *et al.*, 2012). Manure storage is in either an anaerobic lagoon or an external storage facility. In the pit systems, the space may be cleaned from daily to annual intervals, depending on the type utilized. In flush systems, manure is removed several times a day (USEPA, 2001). The pull-plug system removes manure from the pit after being stored for about a week and is then moved to outside storage facilities. This keeps emissions lower within the swine facilities but not necessarily with the later storage of removed manure (Cole *et al.*, 2000). These storage practices result in the decomposition of manure and formation of biogas. Ammonia, hydrogen sulfide, and VOC emissions may be higher in flush systems than from pit recharge and pull-plug pit systems due to turbulence during flushing.

Ammonia

The major air quality concern from swine CAFOs is NH_3 emissions from manure (Cole *et al.*, 2000). Ammonia

Table 3 Summary of emissions from Swine Model Farms (tons per year per 500 animal unit farm)

Type of manure	*Ammonia (NH_3)*	*Hydrogen sulfide (H_2S)*	*Volatile organic compounds*
Flush	15	2.6	0.6
Pit recharge	15	0.9	0.6
Pull-plug with lagoon	15	0.9	0.6
Pull-plug with storage tank	11	NA	NA
Deep pit	12	0.3	NA

Source: Adapted from US Environmental Protection Agency (USEPA), 2001. Emissions from Animal Feeding Operations. EPA 68-D6-0011. Research Triangle Park, NC: USEPA.

concentrations inside confined swine facilities varies widely, from 1.9 ppm to as high as 25.9 ppm and is dependent on the cleanliness of the facility (Duchaine *et al.*, 2000) as well as the time of year and barn ventilation rate (Heber *et al.*, 2000, 2004, 2005). Ammonia emission rates can be affected by housing type, animal size and stage of production, manure management, storage and treatment, feed nitrogen content, and climatic variables (Leneman *et al.*, 1998; Arogo *et al.*, 2003). Ammonia emissions have been found to vary by stage of production. For example, farrowing rooms and nurseries have lower NH_3 emissions than gestation or grow-finish facilities (Zhu *et al.*, 2000; Jacobson *et al.*, 2006). This is due to the higher protein requirement for growing/finishing animals. Zahn *et al.* (2001) studied the ammonia emission rates from 29 swine manure storage systems. These studies showed that deep-pit and pull-plug systems emitted NH_3 at a rate of 57 g NH_3 per square meter per day. On average, lagoons released 85 g NH_3 per square meter per day. Earthen, concrete-lined steel tanks emitted NH_3 at a rate of 144 g NH_3 per square meter per day. These external storage tanks release a significant amount more than the other two systems. The USEPA (2001) confirmed this large NH_3 formation in external manure storage facilities. In general, one of the greatest issues around ammonia in swine production are its effects on the respiratory system leading to irritation of the eyes, skin, mucous membranes, and upper respiratory system.

Hydrogen Sulfide

Hydrogen sulfide forms in deep-pit, pull-plug pit, and in external manure storage management systems (USEPA, 2001). According to Zahn *et al.* (2001), on average, lagoons emitted 0.25 g H_2S per square meter per day; deep-pit and pull-plug systems emitted 0.32 g H_2S per square meter per day; and the eternal tanks emitted 0.95 g H_2S per square meter per day. Once again, the external tanks emitted a significant amount more than the lagoons, and deep-pit and pull-plug systems. In addition to being a health hazard and air pollutant in swine facilities, H_2S contributes to odors, as outlined in the following Odors Section.

Volatile Organic Compounds

In addition to NH_3 and H_2S, Zahn *et al.* (2001) investigated VOC emission rates in 29 manure storage systems. The lagoons systems averaged 63.8 g per VOC syterm per hour; the deep-pit and pull-plug systems emitted 89.9 g per VOC system per hour; and the steel tanks emitted 394 g per VOC system per hour. Other studies have also been performed to quantify VOC emissions from swine facilities. Bicudo *et al.*, 2002 measured the mean VOC emissions at three different swine facilities and found that an 8000-head nursery emitted 204 $\mu g\, s^{-1}\, m^{-2}$, a 2000-head finishing facility emitted 291 $\mu g\, s^{-1}\, m^{-2}$, and a 3000-head finishing facility emitted 258 $\mu g\, s^{-1}\, m^{-2}$. Compared with all manure storage systems, anaerobic lagoons emit the least VOCs and noxious odors (USEPA, 2001).

Odor

Odors from swine CAFOs are primarily comprised of NH_3 and H_2S emissions (Cole *et al.*, 2000; Hamon *et al.*, 2012). Emissions of odors are dependent on seasonal and climatic parameters, as is the case with other CAFOs. Anaerobic processes can also release VFAs that can be considerably more offensive than ammonia or hydrogen sulfide. In terms of manure management, odors increase as the animal manure decomposes (Cole *et al.*, 2000). H_2S creates a very pungent and noticeable sulfur odor. In addition to odor contributions from NH_3 and H_2S emissions, feed composition also plays a direct role in the quantity and intensity of the odors produced (Gralapp *et al.*, 2002). Although NH_3 and H_2S are abundant odors in terms of concentrations in swine CAFOs, approximately 400 different odorous compounds have been identified (Hamon *et al.*, 2012).

Poultry Facilities

Poultry CAFOs include both broiler (chickens used for meat production) and layer (chickens used for egg production) facilities. Broilers are typically produced in littered floor systems, where birds are kept in a closed structure (termed a house) with space to move and access to feed and water systems. Bedding for broiler housing varies by geographical location, but material can include rice hulls, wheat or rye hulls, sawdust or wood shavings, peanut shells, sand, chopped straw, or corn stalks. The bedding used in broiler houses is referred to as litter when it is mixed with feces (USEPA, 2001). Most of the litter is reused (also known as built-up litter) over multiple flocks of production (CAST, 2011). Alternatively, caked litter (i.e., litter that has a wet and hardened surface layer, usually found along the feed and water lines where much of the manure is deposited) is removed between each flock (CAST, 2011; USEPA, 2001). Layer chickens are primarily raised in cage systems, where the birds are housed in cages with a relatively limited amount of space. These can either be in high-rise (HR) (65–70% of cage systems), or manure-belt (MB), (25–30% of cage systems) housing systems (CAST, 2011; Xin *et al.*, 2010) but alternative cage-free housing systems do exist and are increasingly popular. Manure in HR facilities is typically stored in the lower level of the house for 1 year and removed as solid manure in the fall for cropland application. Manure in MB houses is removed daily to weekly, via the MB, and can be stored either on-site, in separate storage, or a composting facility (Xin *et al.*, 2010).

As with other livestock facilities, emissions vary depending on housing and manure management systems. Although a substantial amount of research has been performed to determine air quality emissions associated with on-site production and storage of manure, there is limited data on emissions associated with land-applied poultry manure (a common practice for poultry facilities). Air quality in poultry CAFOs is an area of concern; however, most research is on NH_3, whereas data on other air pollutants, such as PM and VOCs is limited.

Mitigation techniques in poultry facilities are utilized mainly by manure management. Dietary manipulation (Roberts *et al.*, 2007), topical application of chemical or mineral

additives to poultry manure (Li *et al.*, 2008), treatment of exhaust air via a biofilter or wet scrubber (Melse and Ogink, 2005; Manuzon *et al.*, 2007; Shah *et al.*, 2008), and faster application of land-applied manure have been investigated as possible mitigation techniques to minimizing emissions associated with manure from poultry CAFOs. Through direct incorporation, or injection, of manure into soil with immediate tillage there is the potential to minimize emissions from land-applied manure (CAST, 2011). Injection of manure during land application can minimize odors, NH_3, and VOC emissions. In layer facilities specifically the use of MB systems should be used for manure management because they significantly reduce odors and NH_3 emissions (Fournel *et al.*, 2012).

Ammonia

Among both layer and broiler CAFOs, NH_3 is the major noxious gas produced. The primary source of NH_3 from poultry is from manure, both in-house and off-site. Manure excreted from poultry has a high MC and as the moisture evaporates, NH_3 is emitted (USEPA, 2001). The generation and concentration of indoor NH_3 is influenced by housing and manure management practices, as with other livestock CAFOs. Broiler manure storage is in-house, so continuous airflow from ventilation systems is used to help minimize the amount of NH_3 exposure for animals, as NH_3 is emitted year round (USEPA, 2001). However, this does not minimize NH_3 emissions; rather it likely leads to elevated emissions of NH_3 to the atmosphere (CAST, 2011). Manure management in layer housing systems that utilize manure belts allows manure to dry to between 30% and 60% MC, making it easier to transport and creating less NH_3 emissions (Xin *et al.*, 2010). Ammonia concentrations in MB housing are generally lower than in other housing systems (Green *et al.*, 2009) due to the higher frequency of manure removal (Green *et al.*, 2009). Long-term broiler manure storage with high MC can further mineralize organic nitrogen to NH_3 (USEPA, 2001). Though only a small amount of research has been performed in regard to land-applied poultry manure, NH_3–N losses from land-applied poultry manure (expressed as a percentage of manure nitrogen content) have been estimated at 7% for dry laying-hen manure (Lockyer and Pain, 1989), 41.5% for wet laying-hen manure (Lockyer and Pain, 1989), and 25.1% for broiler litter (Cabera *et al.*, 1994). Prolonged exposure to elevated NH_3 concentrations adversely affects bird health, such as the respiratory system and productivity (e.g., feed intake, bodyweight gain, egg production, and feed conversion) (CAST, 2011). For poultry housing, the recommended indoor NH_3 concentration is less than 25 ppm (MidWest Plan Service, 1990; United Egg Producers, 2010).

Hydrogen Sulfide

With dry manure collection from poultry and the associated manure storage facilities, any sulfur excreted should be oxidized to nonvolatile sulfate, thus making H_2S production negligible (USEPA, 2001). Hydrogen sulfide emissions are varied because of MC, the time manure stays in the facility, the ventilation rate, and incidence and duration of storage (USEPA, 2001). In broiler facilities, daily mean H_2S concentrations have an inverse relationship to house ventilation rates and molting of birds causes these H_2S concentrations to decrease (Ni *et al.*, 2012). There is little information about H_2S emissions from layers but averages of 19.7 ppb H_2S have been reported for commercial layer houses, 26.4±17.6 and 24.9 ±19.0 ppb for HR houses, and 40.0±21.1 and 41.2±31.5 ppb MB houses (Lim *et al.*, 2003; Ni *et al.*, 2012, respectively). Higher concentrations of H_2S have been reported to be approximately 40–100 ppb in some broiler facilities (Zhu *et al.*, 2000). Poultry H_2S emissions are much lower than those from other livestock, such as swine (Zhu *et al.*, 2000). If there is residual H_2S in poultry manure at the time of land application, it is oxidized to sulfate but with transient saturated soil conditions sulfate can be reduced back to H_2S and be aerosolized (USEPA, 2001).

Volatile Organic Compounds

Poultry manure is also a contributor to VOCs which, as mentioned in the Section Air Pollutants, can contribute to ozone and odor formation. The high MC of poultry manure leads to the production of VOCs (USEPA, 2001). Poultry manure forms different dienes, ketones, aldehydes, and aromatics, with an overall contribution of 36.43±26.57 ug m^{-3} of total VOC from animal sources (Howard *et al.*, 2010b). The overall contribution from poultry has been found to be significantly less than contributions from cattle or swine (Howard *et al.*, 2010b). Poultry litter composting also contributes to VOC emissions. Composting of poultry litter has been found to emit high amounts of alkanes and alkylated benzenes, with much lower emissions of aldehydes, terpenes, and ketones (Turan *et al.*, 2007). The greatest production of VOC emissions occur early during the composting process and declines rapidly thereafter with the maximum production of VOCs obtained within the first 5 days (Turan *et al.*, 2007).

Odor

Odor associated with poultry is often a result of manure and the most noxious odor has been identified as ammonia (CAST, 2011). Although there is odor associated with poultry CAFOs, its incidence is much less than that of swine facilities and is produced at constant concentrations throughout the day (Zhu *et al.*, 2000). In layer facilities the use of MB systems, both forced air drying and natural drying, reduces odor emissions, respectively, by 37% and 42% compared with odor emissions from a deep-pit technique (Fournel *et al.*, 2012). MB systems also produce less odor than deep-pit systems due to their frequent manure removal (Fournel *et al.*, 2012). Odor incidence in poultry increases as a result of higher temperatures during summer months, and odor varies depending on the age of birds and the season (Fournel *et al.*, 2012; Hayes *et al.*, 2006). Odor from broiler facilities is associated with litter and worsens when the litter is damp (Hayes *et al.*, 2006). Broiler house odors of the same concentration are perceived as more intense than odors emitted from pig slurry and there is a greater correlation between poultry manure odor intensity and

concentration than in swine (Misselbrook *et al.*, 1993). Composting of litter also produces odor as organic compounds can be volatilized during composting (Turan *et al.*, 2007).

Conclusion

As the global human population rises and the degree of affluence in developing nations grows, people demand more food and in particular more high quality animal protein. This demand for protein requires intensification of animal facilities in order to maximize production on limited land. CAFOs have become the main mode for efficient animal production in the US. However, the high stocking density of CAFOs leads to greater amounts of air pollutants and a rise in associated concerns. Additionally, manure and feed storage and management have been a recurring contributor to air quality issues in all three CAFOs. Dairy, beef, swine, and poultry CAFOs all emit NH_3, H_2S, VOCs, and odors, and these air pollutants can impact human and animal health. Numerous approaches to mitigate emissions are currently being studied and include improvements of animal production efficiency, herd health, nutrition, and feed production, as well as manure management strategies.

Introduction: Agriculture and Land Use

The earth's climate is warming as a consequence of the accumulation of greenhouse gases in the atmosphere. The most important greenhouse gases contributing to this warming are carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O). Although these gases are present in the atmosphere naturally, human activity has been responsible for a rapid increase in their concentration over the past century. Greenhouse gases are released by a variety of processes, the most important of which is fossil fuel consumption, which currently adds more than 9 billion tons of CO_2–C to the atmosphere each year. However, other activities make a significant contribution to greenhouse gas emissions, including agriculture. Approximately 31% of annual global greenhouse gas emissions resulted from agriculture and land use according to the Intergovernmental Pannel on Climate Change's fourth assessment report (IPCC, 2007). Globally, agricultural land occupies approximately 40% of the earth's ice-free land area. This land includes land used for crop and livestock production, managed grassland, agroforestry, and bioenergy crop production. But agriculture is currently at a crossroad, challenged by the demands to produce more food for a growing global population, but in ways which reduce environmental impacts, and at a time of water and energy shortages, climate change, and limited availability of new land (Godfray *et al.*, 2010).

The predicted rise in the human population to more than 9 billion people by 2050, as well as changing global diets, will lead to an increased demand in the amount and type of food produced. This will, in turn, lead to the possibility of increased greenhouse gas emissions. One solution to the problem of producing more food (and one that has been used in the past) would be to bring more land into agricultural production. However, the availability of land is limited and there is competition for land to provide other ecosystem services such as the provision of habitats for biodiversity, carbon storage, and cycling of water and nutrients. Small areas of land will undoubtedly be converted for agricultural use, but this will not form the basis for any significant increase in the world's food supply. Instead, more food should be produced from the current agricultural areas and it should be done in ways that reduce environmental impact. The concept has been described as Sustainable Intensification (Godfray *et al.*, 2010) and is proposed as a guiding principle that addresses the twin concerns of maintaining production in ways that will contribute to long-term sustainability in farming systems and thus include greenhouse gas mitigation.

The greenhouse effect is a natural process without which life on the earth would not be possible because the average global temperature would be well below 0 °C. Carbon dioxide and other greenhouse gases absorb infrared radiation from the sun, which causes the greenhouse gas molecules to vibrate. The infrared radiation from the sun is converted into heat energy and is reemitted back into the atmosphere. The heat energy is trapped in the earth's atmosphere and oceans, causing the earth to warm up. There has always been a balance between processes which produce and remove CO_2 from the atmosphere; thus, the earth's temperature has remained relatively stable. Recently, humans have altered this balance, resulting in increasing levels of CO_2 in the atmosphere. This has resulted in more heat energy becoming trapped in the earth's atmosphere, leading to a rise in average global temperatures (IPCC, 2007).

This article focuses specifically on the relationships between agricultural production and greenhouse gas emissions. The management and reduction of greenhouse gas emissions from agriculture makes a critical contribution to sustainable land use, because such management can influence both the production and environmental impact of the system. Farming is responsible for the production of three greenhouse gases: CO_2, N_2O, and CH_4 (**Figures 1(a)** and **(b)**). Each gas contributes to the warming up of the atmosphere; however, the warming potential of each gas varies. Nitrous oxide, although produced in small quantities, has the largest warming potential with a value 298 times greater than that of CO_2 over a 100-year period. Methane's warming potential is 25 times greater than that of CO_2 over a 100-year period. By comparing the ability of each gas to contribute to warming of the atmosphere, their collective impact can be compared by converting the warming potential of each gas to CO_2 as CO_2 equivalents or CO_{2e}.

Carbon dioxide production from agricultural sources is mainly derived from land-use change. A change from forest or permanent pasture to cultivated croplands often involves a loss of soil carbon, as soil organic matter is decomposed and released to the atmosphere as CO_2. Atmospheric CH_4 concentrations are partly driven by agricultural activity and CH_4 is mainly a product of manure, ruminants, and rice cultivation; since the early 1990s, growth rates of the gas have declined (IPCC, 2007). Agriculture is the primary driver of increased N_2O emissions, through the use of synthetic fertilizers increasing available nitrogen supply to agricultural systems (Reay *et al.*, 2012). A shift in diet toward higher meat consumption has lead to an increased need for intensification of land management practices and expansion to produce increased feed needed for consumption by livestock. Between 1967 and 1997, meat demand in developing countries has more than doubled, rising from 11 to 24 kg per capita per year (Smith *et al.*, 2007). This pattern is expected to continue particularly in countries such as China, linked to economic growth and shifting lifestyles, which will lead to a large increase in greenhouse gas emissions. A shift to higher meat consumption would also increase emissions of CH_4 due to its association with ruminants. A combination of shifting diet and increased demand for food due to population growth are expected to drive an increase in future greenhouse gas emissions from agriculture. Mitigation measures may help to buffer these emissions.

The total global emissions of greenhouse gases from agriculture in 2012 has been estimated to be 4.68×10^{15} g CO_{2e}

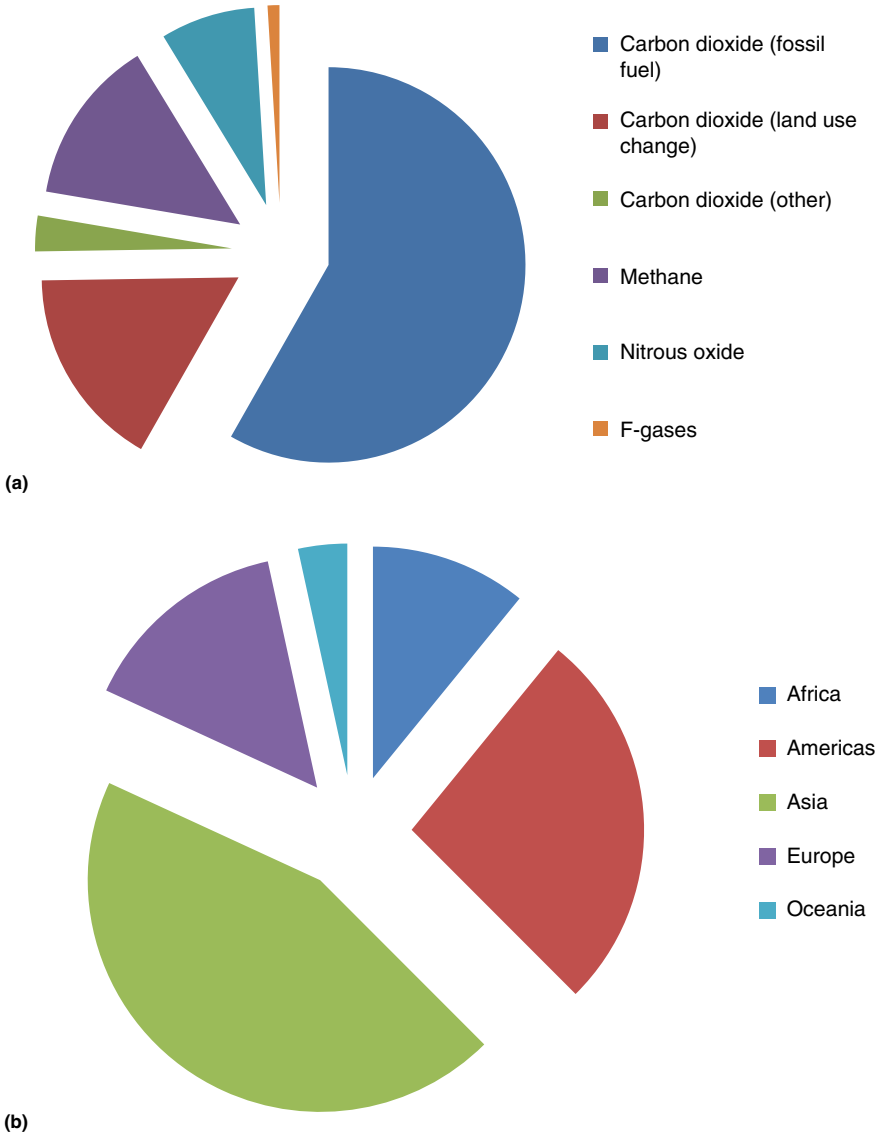

Figure 1 (a) Total global greenhouse gas emissions in 2004 and (b) global emissions from agriculture between 2000 and 2010 (FAO, 2012). F-gases, fluorinated gases. Reproduced from Food and Agriculture Organisation's Statistical Database; FAOSTAT. Rome. Reproduced from data reported by the IPCC (2007). Summary for policymakers. In: Solomon, S., Qin, D., Manning, M., *et al.* (Eds.), Climate Change 2007: The Physical Science Basis. Contribution of Working Group I to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change. Cambridge, UK and NY, USA: Cambridge University Press.

(FAO, 2012). This has grown by 13% over the two decades between 1990 and 2010. However, the rate of growth has been highly uneven, with strong growth in emissions from agriculture from non-Annex 1 countries (including Asia and South America), occurring at the same time as Annex 1 countries (that includes North America and Europe) showed a small decline in emissions (Figure 2).

Reporting

The reporting of emissions of greenhouse gases from agriculture and other emission sources is guided by methodologies developed by the IPCC (2006). In accordance with these guidelines, emissions from sources are calculated on the basis of emission factors or coefficients, which provide estimates of emissions from typical management practices and activity data describing fertilizer use, livestock numbers, etc. Varying levels of sophistication are possible, depending on the availability of national data and information. The estimation of emissions of greenhouse gases from agricultural activities presents particular challenges that are a consequence of the interactions between the environment and the underlying biological processes responsible. Emissions represented by such calculations inevitably represent an approximation and could be considered to be at best an average over a given time period. The emissions are reported to the United Nations

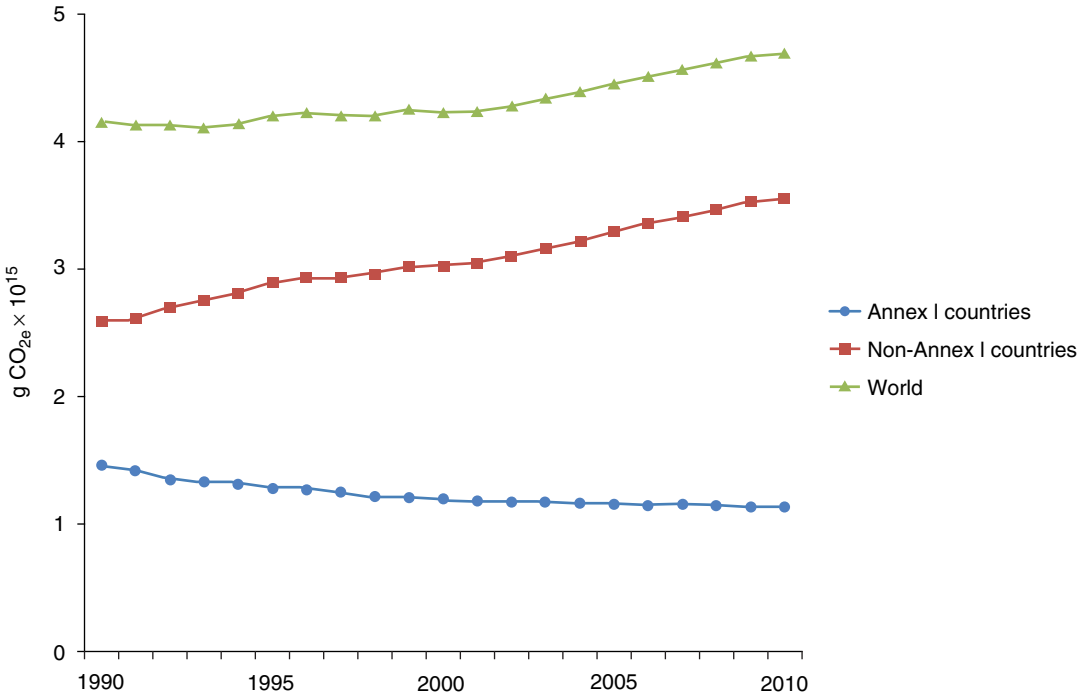

Figure 2 The changes in emissions of total greenhouse gases from agriculture at a global scale between 1990 and 2010. Annex I, North America and Europe; Non-annex I, Asia and South America. Reproduced from FAO, 2012. Food and Agriculture Organisation's Statistical Database, FAOSTAT. Rome. Available at: http://faostat3.fao.org/ (accessed 24.01.14).

framework on climate change and synthesized to produce reports on global emissions.

The diversity of processes contributing to greenhouse gas emissions from agriculture, and their biological sources, makes direct measurement difficult. However, because of the significance of agriculture in contributing to global greenhouse gas emissions, a significant amount of work has been undertaken to develop methodologies that can be used to make direct measurements of emissions. This work helps us to quantify more accurately the magnitude of emissions, to develop models that are better able to represent such emissions, and to devise mitigation strategies that are effective both in terms of reducing greenhouse gas emissions and maintaining productivity.

Measurement/modeling

A variety of methodologies are available for the measurement of greenhouse gases from agriculture, ranging from small-scale measurements from individual sites in fields to atmospheric measurements across regions. For example, emissions of N_2O can be made by placing sealed chambers at the ground surface and measuring the accumulation of gases over a short period of time (usually less than 1 h). An alternative (micrometeorological) approach is to use sensors attached to masts above the ground surface, coupled with measurements of instantaneous wind speed and then calculate fluxes using an appropriate model (Jones *et al.*, 2011). Measurement of methane emissions from livestock can be undertaken by direct sampling of animal breath and also by using the micrometeorological approach described for N_2O. An alternative methodology that has been valuable in quantifying livestock emissions is to use chambers within which animals can be housed, and then measure changes in gaseous composition of the atmosphere passing through them.

Accurate measurements of greenhouse gas emissions are critically important in developing predictive models of greenhouse gas emissions. These vary in complexity from simple empirically based models estimating individual emissions associated with specific management practices to complex whole ecosystem models that represent interactions between management and the environment to simulate emissions of CO_2, N_2O, and CH_4.

Nitrous Oxide

Nature of Gas

The trace gas N_2O makes a significant contribution to the earth's greenhouse gas balance, and agriculture is its main source (Reay *et al.*, 2012). Concentrations of N_2O have increased steadily in the atmosphere in recent decades, primarily as a consequence of emissions from soils that are caused by microbial transformations of fertilizer nitrogen compounds contained in synthetic fertilizers and organic manures (**Figure 3**). There is a smaller contribution from manure management and biomass burning.

Nitrous oxide is a powerful greenhouse gas with approximately 300 times the global warming potential of CO_2 per molecule (Robertson and Vitousek, 2009); however, it is not emitted at the same magnitude. Nitrous oxide directly contributes to approximately 10% of the total greenhouse gas effect, but atmospheric N deposition also influences the

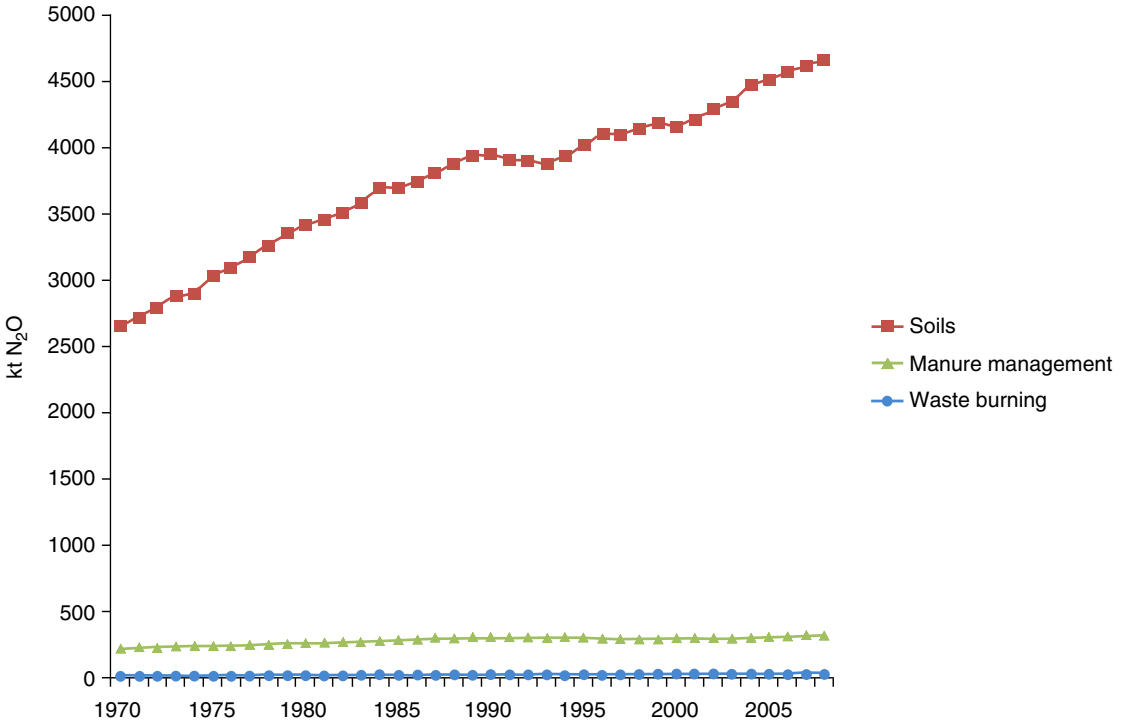

Figure 3 Global emissions of nitrous oxide from agriculture between 1970 and 2008, partitioned by source. Reproduced from European Commission, Joint Research Centre (JRC)/Netherlands Environmental Assessment Agency (PBL), 2011. Emission Database for Global Atmospheric Research (EDGAR), release version 4.2. Available at: http://edgar.jrc.ec.europa.eu (accessed 24.01.14).

greenhouse gas budget more widely through indirect effects on the cycling of C. Although N_2O does absorb the earth's outgoing infrared radiation, it is not chemically reactive in the troposphere (the lower layer of the atmosphere). However, its chemical reactivity increases as it enters the stratosphere (the layer of the atmosphere between 12 and 46 km above the earth's surface), where it plays a major role in stratospheric ozone depletion. Nitric oxide and nitrogen dioxide (collectively referred to as NO_x) are produced from the dissociation of N_2O in the atmosphere; these compounds then react readily with ozone, leading to its depletion in the stratosphere (Ravishankara *et al.*, 2009). Somewhat paradoxically, NO_x is also responsible for the production of ozone in the troposphere, which causes many environmental problems for the health of flora (including crops) and fauna (including humans). Ozone at ground level also leads to photochemical smog, which can be a problem in both urban and rural areas.

The emission of N_2O is, therefore, of critical importance in both tropospheric and stratospheric chemistry and is an important source of air pollution (Sutton *et al.*, 2011). The residence time of N_2O in the atmosphere is quite long (approximately 120 years) and wind currents can transport the gas to vast distances. Air pollution is not limited by national boundaries.

Cycling (Sink Source)

The nitrogen cycle involves large-scale global transfers of N between the atmosphere and the biosphere. Nitrogen inputs to the biosphere occur both as a consequence of natural processes (biological fixation and lightening) and industrial fixation (**Figure 4**). Nitrogen is ultimately returned to the atmosphere as nitrogen gas, but the processes of microbial transformation of N result in the release of small quantities of N_2O. There are natural and anthropogenic contributors to atmospheric N_2O emissions, both of which occur primarily as a consequence of microbial transformation of N in soils and water. Natural sources result from nutrient cycling processes in unmanaged ecosystems, whereas anthropogenic sources are derived from microbial transformations of N applied to agricultural land in fertilizers, manures, and crop residues.

Other agricultural practices also influence the output of N_2O from cultivated or grazed lands, such as water management, aeration, application of alternative fertilizers (ammonium nitrate, urea, cattle slurry, chicken manure, and sludge pellets) burning, biological nitrogen fixation, grazing, tillage, crop rotation, and decomposition of crop residue. The application of nitrogen to land is used to support both arable crops and pastures.

Nitrous oxide is produced as an intermediate during the microbial processes of nitrification and denitrification. The microbial transformation of inorganic nitrogen is the main source of N_2O in the soil, and so substrate supply is a determinate factor in emission rate (Butterbach-Bahl *et al.*, 2011). Nitrification involves the oxidation of ammonium (NH_4^+) to nitrate (NO_3^-), whereas denitrification is a reductive process resulting in the reduction of NO_3^- to N_2 gas via a series of intermediates during microbial respiration. Nitrous oxide emitted from the soil can be an outcome of

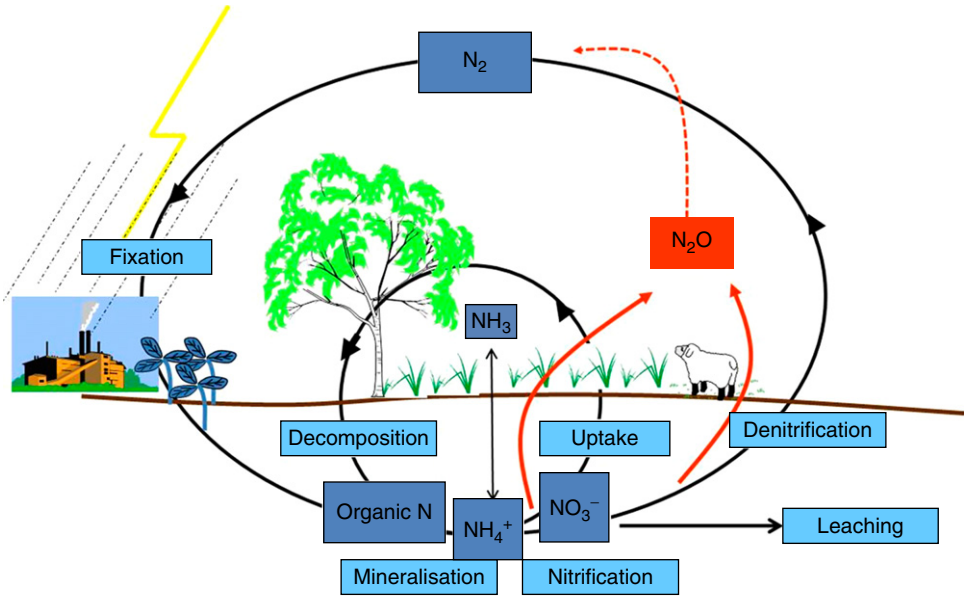

Figure 4 A simplified schematic diagram of N cycling in agricultural systems. Nitrogen pools are represented by the purple boxes and processes are indicated by the light blue boxes.

nitrification, denitrification, or a combination of the two. The denitrification process ultimately leads to the complete reduction of N_2O to N_2 in the atmosphere. Numerous variables regulate the transformation reaction as well as the proportionality of gas products, such as soil pH, oxygen content of the soil, temperature, carbon availability, and nitrate or nitrite concentrations (Butterbach-Bahl *et al.*, 2011). Addition of fertilizer directly increases available nitrogen leading to higher nitrification and denitrification rates and so enhanced rates of N_2O production by the system (Mosier *et al.*, 1998). Emissions are greatly increased immediately after nitrogen application to crops and soils, when a large outward flux of nitrous oxide occurs. Rates of N_2O production and subsequent emission from the soil to the atmosphere are heterogeneous, both spatially and temporally (Rees *et al.*, 2012). Site-specific variables are determinate factors in the rate and magnitude of N_2O emissions, such as soil water content, texture, and compaction. The availability of nutrients, microbial activity, soil temperature, and soil aeration status are all determined variably by soil water content and so effect N_2O emissions from the soil.

The IPCC (2007) reported that global atmospheric N_2O concentrations had increased from a preindustrial value of approximately 270–319 ppb in 2005. Anthropogenic sources account for less than half global N_2O emissions globally; however, they are the primary driver in emission growth. Global reactive N supply has approximately doubled relative to the preindustrial average through the manufacturing of synthetic fertilizers, use of manure, and the enhancement of biological nitrogen fixation as well as industrial uses (Reay *et al.*, 2012). Manure usage would have been the predominant source of N_2O production before the Second World War. The subsequent rapid increase in synthetically manufactured fertilizers in the second half of the twentieth century led to a rapid increase in N_2O emissions. During the past 40 years, unprecedented additions of nitrogen have been made to agricultural systems (Erisman *et al.*, 2008). In 2005, 100 Tg of synthetic N was applied to the world's agricultural systems. However, only 17 Tg of N was consumed by humans in food, indicating that much of the applied N is lost through various pathways to the environment (Erisman *et al.*, 2008). As the global human population continues to rise, food must be produced to sustain it, but it will be increasingly important to use added nitrogen more efficiently.

Geography and Emission Intensity

The patterns of fertilizer consumption and associated production of N_2O vary considerably on a global basis. Over the past 40 years, India and China have shown a strong growth in emissions, whereas those from developed nations such as the United States of America and the United Kingdom remain stable (**Figure 5**). N_2O emissions derived from agricultural source are expected to rise from approximately 87 Tg N_2O–N per year in 2000 to 236 Tg N_2O–N per year by 2050, representing a 270% increase (Tilman *et al.*, 2001), primarily derived from increased nitrogen fertilizer use in non-OECD Asia, Latin America, and Africa (Reay *et al.*, 2012), as well as a potential increase in biofuel usage. Regional variability in N_2O emissions is expected to continue, with Asia being the primary contributor due to its population levels (Rees, 2011). Projected shifts to a higher meat consumption diet will also contribute to higher emissions, particularly from Asia. There are currently large differences in sources of N_2O emissions across the world regions. In Europe, Asia, North America and, Central and South America, direct emissions from soils dominate contributions, but in Africa and Oceania, manure and pasture management are the primary contributors. Fertilizer application patterns show clear geographic trends. Higher application rates are apparent in Asia, Europe, and North America, whereas lower rates occur in Africa, Latin America, and Oceania. Lower application rates are associated with more extensive areas of land management but may also indicate

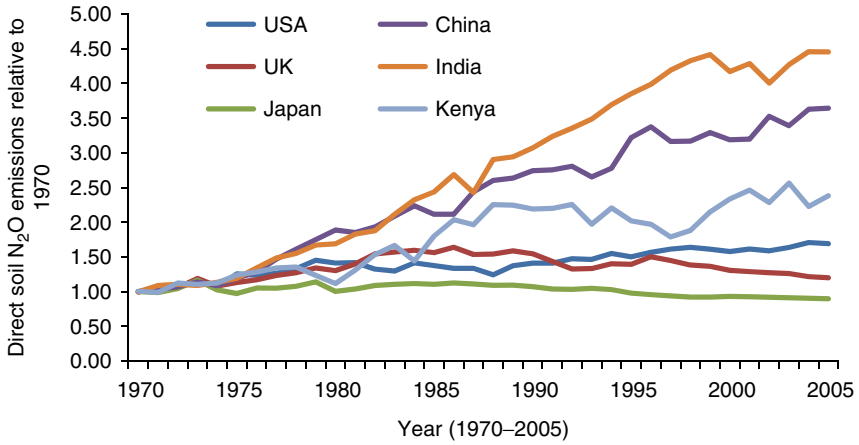

Figure 5 Comparison of N_2O emissions for different nations relative to 1970. levels. Reproduced from European Commission, Joint Research Centre (JRC)/Netherlands Environmental Assessment Agency (PBL), 2011. Emission Database for Global Atmospheric Research (EDGAR), release version 4.2. Available at: http://edgar.jrc.ec.europa.eu (accessed 24.01.14).

lower productivity. The relationship between emissions and the population size of a given region can be expressed by dividing total national emissions by the population size. Asia has the lowest N_2O emissions per capita of all continents at 623 g, which is very low relative to North America's 2167 g per capita. Per capita emissions are largely related to meat consumption, which explains the extent of North America's per capita emissions; this trend is expected to develop in Asia in the future due to the association of meat consumption with an expected increase in wealth (Rees, 2011).

Mitigation

Mitigation options for N_2O emissions generally aim to increase the efficiency with which fertilizer N is used by crops and thereby reduce the potential for losses. This can be achieved by improving soil conditions, for example, by improved drainage and soil structure. Other approaches focus on reducing the presence of available N in soils by altering the timing of fertilizer applications to better match crop demand or by reducing overall N inputs. The use of a winter crop cover and species introductions can also help to reduce emissions by making more efficient use of added N. Legumes offer an important opportunity to reduce greenhouse gas emissions, because they are able to fix atmospheric nitrogen biologically and release less N_2O than fertilizer nitrogen. Another interesting approach has been to use inhibitors that slow down the nitrification process and therefore have the potential to both reduce N_2O production and increase crop N uptake. Although such additives are expensive, they have been widely used in New Zealand to reduce N_2O emissions and increase fertilizer-use efficiency.

Demand side measures also have the potential to reduce N_2O emissions, because meat consumption is strongly linked to N_2O production. Improved efficiency of the food system and avoiding food loss and wastage are viable options which could substantially reduce emissions. To assess both the potential magnitude of results as well as the cost of different mitigation options, marginal abatement cost curves can be utilized (MacLeod *et al.*, 2010). Different mitigation approaches have differential impacts on emissions, as well as incurred cost, with some measures saving both money and emission. Mitigation strategies should integrate measures in order to achieve maximum reductions; not overlooking that cost-effectiveness of specific strategies may change over time as well as not overlooking a possible interaction between measures. The effectiveness of mitigation measures are often site specific, which can cause difficulties when scaling up; there is high variability in response to measures by different soil type and climate. To overcome this, spatially explicit farm management practices (precision farming) can allow the integration of mitigation measures to achieve maximum reductions overcoming problems of spatial heterogeneity (Rees *et al.*, 2013).

Methane

Nature of the Gas

Methane (CH_4) is a principal component of natural gas. It is a simple molecule that consists of four hydrogen and one carbon atom, and at 1.8 ppm, it is the most abundant non-CO_2 greenhouse gas in today's atmosphere (Montzka *et al.*, 2011). Methane is a powerful greenhouse gas with a global warming potential 25 times greater than that of CO_2, and it plays a central role in tropospheric chemistry. Like N_2O, concentrations of CH_4 have increased significantly in recent decades (**Figure 6**). However, unlike N_2O, CH_4 is produced by a much wider variety of sources. Methane is relatively stable in the atmosphere and remains there for approximately 9–15 years.

Sources

A major source of CH_4 emissions from agriculture is the enteric fermentation of ruminant livestock (IPCC, 2007). In domesticated ruminant livestock, CH_4 is generated as a result of the complex microbiological fermentation in the rumen and the large intestine and is released via the mouth or nostrils. The process of enteric fermentation is a microbial

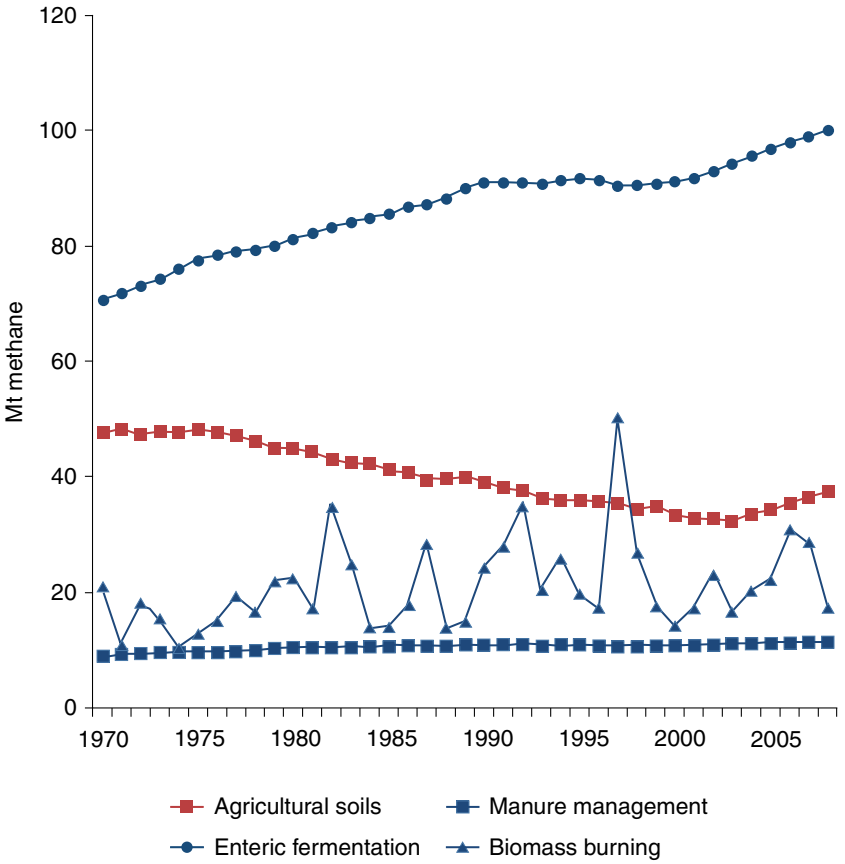

Figure 6 Global methane emissions from agricultural sources apportioned by source between 1970 and 2008.

fermentation process that produces methane as a by-product. The pattern and magnitude of these emissions may vary with grazing behavior and diet (USEPA, 2006). Methane emissions from ruminant livestock have increased significantly in recent years as a consequence of larger numbers of livestock on a global basis (**Figure 6**).

Another major source of CH_4 results from rice cultivation by the anaerobic decomposition of organic matter in soil (Li *et al.*, 2005). Soils that are flooded are ideal environments for the production of CH_4 as they have high levels of organic substrates in anaerobic conditions, with high levels of moisture. These conditions promote anaerobic respiration, which is the process responsible for CH_4 production. The magnitude of emissions may vary with soil conditions, production practices, and the climate.

Methane emissions released by biomass burning result from an incomplete combustion of organic substrates and encompass a wide variety of sources (i.e., woodlands, peat lands, and agricultural waste) (Cloy *et al.*, 2012). Higher CH_4 emissions may result from the burning of the latter two, due to a high water content and low oxygen availability common to the combustion of these fuel sources (USEPA, 2006).

Another source of CH_4 is produced from livestock manure management systems, when organic material is decomposed in anaerobic conditions. In particular, liquid manure management systems (i.e., lagoons or holding tanks) that are often used in larger swine and dairy operations, can contribute significantly to CH_4 emissions (USEPA, 2006). Methane is also produced from buried wastes in landfill sites and as a result of leakage from gas production and transport. There are also significant natural sources of methane from termites and wetland ecosystems.

Sinks

Once methane is released, it is removed from the atmosphere by atmospheric consumption processes or sinks. The amount of CH_4 released and removed ultimately determines atmospheric CH_4 concentrations and thus how many years they will remain in the atmosphere. Global CH_4 sinks arise primarily from the oxidation by chemical reaction with hydroxyl radicals (OH) in the atmosphere (IPCC, 2007). In the tropospheric layer of the atmosphere, CH_4 reacts with OH to produce CH_3 and water.

Methane is also removed from the atmosphere (though in smaller amounts) through stratospheric oxidation. From both processes, small amounts of CH_4 are destroyed by reacting with the OH in the atmosphere, and this accounts for approximately 90% of methane removal from the atmosphere (IPCC, 2007). Other CH_4 sinks include the microbial uptake in soils as well as reaction with chlorine atoms in the atmosphere. These sinks contribute an estimated 7% and 2% of the total methane removal, respectively.

Growth Rate

Records of ice sheets indicate that CH_4 is more abundant in the earth's atmosphere now than at any time during the past 400 000 years (IPCC, 2007). Global average atmospheric concentrations of CH_4 have increased since 1750, from approximately 700 to 1745 parts per billion by volume (ppbv) in 1998, which equates to a 150% increase. Since 1998, CH_4 emissions have increased, but the overall rate of CH_4 growth has reduced. A recent study by Bergamaschi *et al.* (2010), highlights that atmospheric CH_4 has been at a relatively steady state of 1751 ppbv between 1999 and 2002. The IPCC (2007) estimated that CH_4 emissions increased by approximately 17% between 1990 and 2005, with an average annual increase of 58 Mton CO_2 equivalents per year.

Anthropogenic sources account for less than half global CH_4 emissions; however, they are the primary driver in emission growth. Agriculture is the largest man-made source of CH_4, which contributes approximately 43% toward total anthropogenic emissions of CH_4 (Cloy *et al.*, 2012). This can be accounted for by an increase in population pressure (also an increase in demand for food, hence more meat and dairy products), technological change, public policy, and economic growth (increased gross domestic product particularly in some developing countries) (IPCC, 2007). These emissions mainly derive from large sources such as enteric fermentation by ruminant animals (25%) and rice cultivation (12%), with minor contributions from animal waste (3%) and savannah (biomass) burning (3%) (Cloy *et al.*, 2012).

Future projections highlight the potential for further increases in CH_4 emissions. For example, the Food and Agriculture Organization has estimated that if emissions increase in proportion to increases in livestock numbers, then global livestock-related methane production is expected to increase by up to approximately 60% (Steinfeld *et al.*, 2006). This prediction is feasible, particularly in developing countries such as South America, as cattle population has increased from 176 to 379 M head between 1961 and 2004 (IPCC, 2007). Further, all other livestock categories have increased in the order of 30–600% since 1961, which has been primarily due to food demand and is projected to increase further in the future years. The USEPA (2006) predicts that combined CH_4 emissions from enteric fermentation and manure management will increase by 21% between 2005 and 2020.

Geography and Emission Intensity

Methane emissions from developing regions such as Africa, Asia, and Latin America have recently shown strong growth, whereas in Europe and North America, emissions remain relatively stable (with smaller fluctuations). Emissions are projected to increase by as much as 60% by 2030 (USEPA, 2006). This is more likely to be accounted for by emissions from Asia, which are expected to show an increase from animal sources, a 153% increase from enteric fermentation and 85% increase in manure management in particular from 1990 to 2020 (IPCC, 2007, USEPA, 2006). Latin America is expected to contribute significantly toward the global increase of CH_4 emissions as it is projected to increase emissions by 51% between 1990 and 2005 (USEPA, 2006). This is largely due to increased food demand and population pressures that will most likely result in increased emissions from agriculture.

The only region where, according to the USEPA (2006), CH_4 emissions are projected to decrease to 2020 is Western Europe. This is associated with numerous emission reduction policies (such as the Kyoto Protocol) that legally bind countries to reduce emissions and other environmental policies (IPCC, 2007).

Mitigation

Opportunities for mitigating CH_4 emissions include effective management of livestock, as more efficient use of feeds often reduces amounts of CH_4 produced (Clemens and Ahlgrimm, 2001). More intensive feeding regimes with a carefully tailored feed (e.g., augmenting the volume of starches in the diet greatly reduces CH_4) and high-quality forage management practices (e.g., livestock grazing on mixed alfalfa-grass pasture) can reduce per capita emissions by up to 50% (Thorpe, 2009). One strategy for reducing methane emissions is to inhibit the production of methanogenesis within the animal husbandry system. Such options include the application of ionophores, methane oxidizers, and probiotics (Thorpe, 2009). However, this method is unlikely on its own to achieve significant mitigation of emissions, may prove uneconomic in the long term (Patra, 2012), and is currently outlawed in the EU. One of the most straightforward CH_4 emissions mitigation opportunities occurs as a consequence of herd reduction, although a less drastic option involves genetic selection and the use of breeds with lower CH_4 emissions (Thorpe, 2009; Bell *et al.*, 2011). The developed world has seen a general decline in herd numbers over the past 20 years. This is a result of increasing concerns over meat consumption and health scares, coupled with concerns over the nature of production (ibid, 2008). Strategies to mitigate emissions from rice cultivation include draining the wetland twice during the growing season, as this can effectively reduce CH_4 release from 10% to 80% (Smith *et al.*, 2008). Kai *et al.* (2011) found that changes in agricultural practices such as new high-yield rice species, coupled with greater application of fertilizers, often require shorter inundation periods which, in turn, can reduce CH_4 emissions.

Carbon Dioxide

Nature of Gas

Carbon dioxide (CO_2) is a naturally occurring color- and odorless chemical compound which exits as a gas at room temperature. The chemical structure of CO_2 consists of a single carbon atom covalently bonded to two oxygen atoms. It has a molecular mass of 44.01 g mol^{-1}, a density of 1.98 kg m^{-3}, and boiling and melting points of −57 and −78 °C, respectively. The ability of CO_2 to dissolve in water makes it a factor contributing to ocean acidification by the formation of carbonic acid (H_2CO_3). The main environmental concern, however, is over CO_2 acting as a greenhouse gas, which is a significant factor contributing to global warming.

Carbon dioxide is widely used by humans throughout many different industries. Common uses are in carbonated drinks (soft drinks and beer), decaffeinated coffee production,

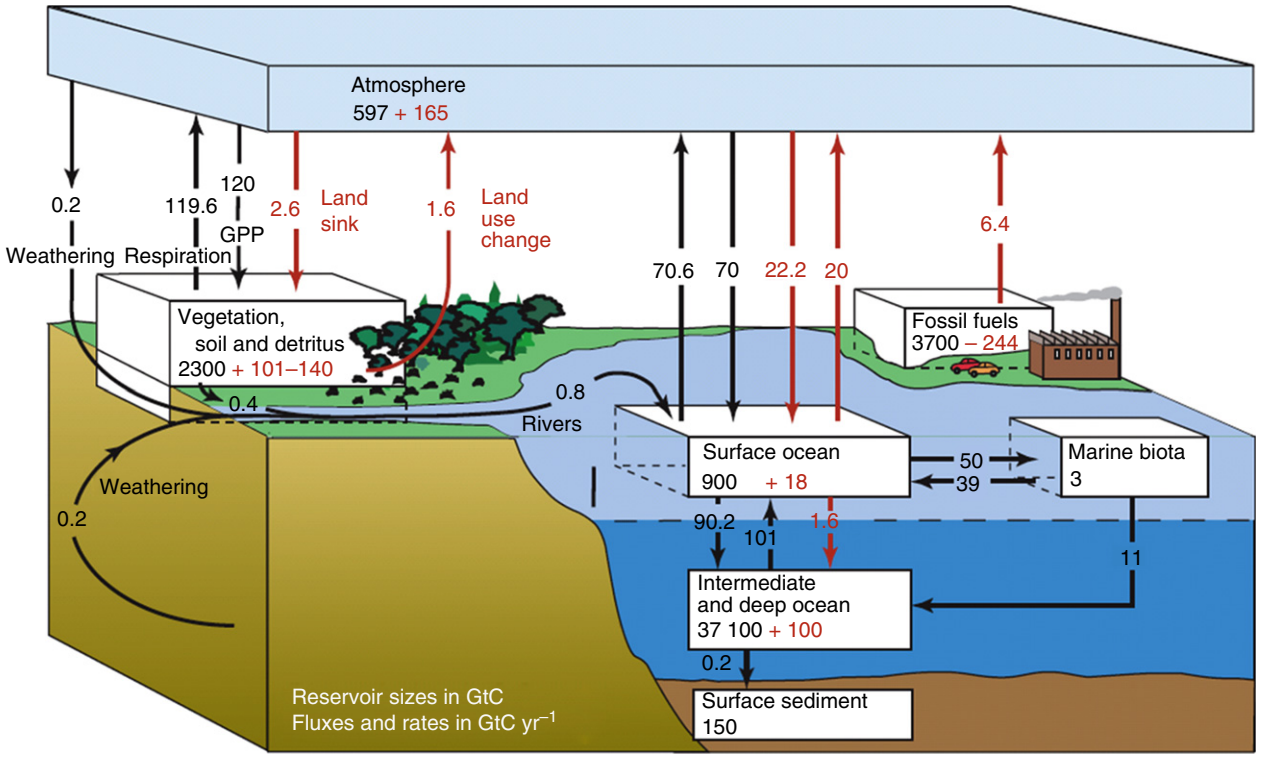

Figure 7 The global carbon cycle (IPCC 2007). Figures in black represent natural processes and pools, whereas those in red represent the contribution of anthropogenic influences. GPP, gross primary production (http://www.ipcc.ch/graphics/ar4-wg1/jpg/fig-7-3.jpg, with permission from IPCC).

wine making, fire extinguishers, as a refrigerant, and to enhance plant growth in greenhouses.

Cycling (Source/Sink)

Carbon moves naturally between land, oceans, and atmosphere via the carbon cycle (Figure 7). The timescales for carbon transformation vary greatly from seconds, such as during fixation of CO_2 via photosynthesis, to more than millions of years, as in the case of fossil carbon formation. Not only are humans responsible for emitting large amounts of greenhouse gases into the atmosphere through the combustion of fossil fuels, but soils also make a significant contribution. The proportion of greenhouse gas emissions from different sectors illustrates that CO_2 emissions directly attributable to agriculture are relatively small, but agriculture, together with land-use change, contributes to almost one-third of global emissions. Despite this large loss of CO_2, there is the ability to use land as a means of reducing atmospheric CO_2 levels by sequestering it in soils. This brings the additional benefit of improved soil quality from organic matter, leading to enhanced agricultural production. Agriculture and forestry are unique in that they can provide both a source and a sink for CO_2.

The two main sources of CO_2 associated with agriculture are the relatively small contribution made by the use of fossil fuels and land-use change. Fossil fuels are needed in agriculture as fuel for farming machinery, in the manufacture of agricultural equipment, and during the production of agrochemicals. Fossil fuel use in agriculture is low in relation to societies' overall energy use, representing only 3–4.5% of the total energy budget of industrialized countries using high intensity farming (Sauerbeck, 2001). The amount of fossil fuel and subsequently CO_2 emissions attributable to agriculture increases dramatically when including food processing, preservation, packaging, and transport. Increasingly, food is being transported further away from where it was grown to where it is consumed.

By contrast, land use change, second only to energy production, is one of the biggest sources of anthropogenic CO_2 into the atmosphere. Deforestation, conversion of forests, grasslands, and drainage of wetlands for agricultural purposes are the largest sources of CO_2 associated with agriculture. Net cumulative emissions of CO_2 from land-use change, from 1850 to 2000, amount to approximately 156 Pg C (Houghton, 2003). Land-use change to agriculture leads to CO_2 being emitted because some of the carbon fixed in the plants during photosynthesis is removed when harvested, resulting in less plant litter and biomass being returned to the soil. This causes disruption of the soil's aggregates and enhanced microbial decay of organic matter, leading to CO_2 release via respiration. Disruption of soil aggregates can cause loss of the carbon-rich topsoil due to an enhanced susceptibility to erosion. Burning organic matter in the form of plant residues during agricultural practices such as slash and burn also causes the release of significant amounts of CO_2.

Agriculture can also act as a sink for CO_2. In carbon-depleted agricultural soils, organic carbon can be enhanced by increasing the addition of carbon in soil from plant litter or crop residues and by reducing the rates of microbial decomposition. Where land has been depleted in carbon, reversion to forestry or pasture can restore carbon stocks and

contribute to a net removal of CO_2 from the atmosphere. The ability of agricultural soils to act as a CO_2 sink is unlikely to continue indefinitely as they approach equilibrium with inputs and losses of carbon in a given environment. Carbon levels in soil can start to decrease in circumstances where management increases loss rates.

Growth Rate

Measurements of atmospheric CO_2 concentrations are very reliable and have demonstrated a long period of annual increase in atmospheric CO_2 concentrations. However, there are uncertainties in the accuracy and quantification of terrestrial and oceanic CO_2 sinks. Growth rates in atmospheric CO_2 concentrations have been recorded in Mauna Loa in the Pacific Ocean since 1958 and were initiated by C. David Keeling of the Scripps Institution of Oceanography in March of 1958 at a facility of the National Oceanic and Atmospheric Administration (Keeling *et al.*, 1976). They show a continuous increase from less than 320 ppm in 1958 to nearly 400 ppm in 2013 (**Figure 8**). Since 1958, the average rate of increase in the atmospheric concentration of CO_2 has been approximately 1 ppm per year (2 PgC per year). In 2005, the atmospheric CO_2 concentration was approximately 380 ppm, which is an increase of approximately 35% since preindustrial times. Between 1959 and 2008, 43% of each year's CO_2 emissions remained in the atmosphere (Le Quere *et al.*, 2009). However, in recent years, this amount has been thought to have risen to up to 45% due to climate change effects. Increasing CO_2 concentrations correlate well with fossil fuel combustion and land-use change patterns.

Emissions per Country

In 2011, China, the United States, the European Union, India, the Russian Federation, and Japan were the top six emitting countries of CO_2, representing 28%, 16%, 11%, 7%, 5%, and 4% of global emissions, respectively (Global Carbon Project, 2012). A large proportion of CO_2 emissions originates from fossil fuel consumption rather than from agriculture (Le Quere *et al.*, 2009).

Since 2002, there has been a 150% increase in total CO_2 emissions from China. However, there is great uncertainty in the accuracy of CO_2 emission reporting from China, with uncertainty levels of 10%, whereas most other industrialized countries have an uncertainty level of 5%. At a global level, large increases in emissions can be linked to thermal power generation, steel production, and cement production. There was a small decline in emissions linked to the economic slowdown of 2008–09, but growth in emissions soon recovered after that reaching more than 9 billion tons of CO_2–C by 2010 (Peters *et al.*, 2012).

In 2011, the Organisation for Economic Co-operation and Development (OECD) countries accounted for one-third of global CO_2 emissions, the same amount as that of China and India combined. In 2011, CO_2 emissions from developed countries decreased. The European Union, the United States, and Japan experienced decreases in CO_2 emissions of 3% to 3.8 billion tons, 2% to 5.4 billion tons, and 2% to 1.2 billion tons, respectively. The decrease in emissions is thought to have been due to weak economic conditions, mild winter weather, and high oil prices (Andres *et al.*, 2012). Despite this, developing countries increased emissions by 6% on average in

2011. Australia, Spain, Russia, and Canada experienced increases of 8%, 2%, 1%, and 7%, respectively. Economies in Transition countries also experienced an increase in emissions such as in Ukraine, where emissions increased by 7%. Total CO_2 emissions for all industrialized countries that had quantitative greenhouse gas mitigation targets under the Kyoto Protocol decreased in 2011 by 0.7%. Figure 4 shows CO_2 emissions per capita from combustion of fossil fuels and cement production of the top 5 emitting countries in 2011. China and the European Union have similar per capita emissions.

Mitigation

Reducing increases in atmospheric CO_2 accumulation as a result of agriculture and land-use change requires a commitment to avoiding land-use change that will release large amounts of soil carbon. In particular, this must address deforestation, cultivation of pasture, and degradation of peaty and organic soils. Such actions would help to avoid the increases in atmospheric CO_2 that have been a characteristic of the past century of human development; however, this also requires recognition of the range of functions that land supports in addition to food production.

The management of agricultural soils also provides an opportunity to increase the quantities of carbon stored in soils that are used on a continuous basis for agricultural production. These include improved nutrient management, reduced tillage, improved agronomy, the use of composts and manures, improved rotations, and bioenergy crops. The efficiency of different management options varies according to climate and baseline agricultural practices; however, it has been estimated that in Europe, there is a potential through improved agricultural management to sequester between 90 and 120 Mton carbon per year, with benefits in terms of greenhouse gas mitigation and improved soil quality (Smith, 2004).

Conclusions

Agriculture, and the land use associated with agricultural production systems, contributes significantly to global greenhouse gas emissions. Most emissions are associated with N_2O emissions from N fertilizers and manures and from CH_4 emissions from ruminant livestock and rice cultivation. A smaller amount of emission is also associated with CO_2 loss from soils converted into croplands from forests and pastures. There is an urgent need to improve the efficiency of farming systems in order to ensure that productivity is maintained or increased at the same time as their environmental impact (particularly greenhouse gas emissions) are reduced. Many management options are available to reduce the emissions of individual greenhouse gases in the crop and livestock sectors. The implementation of such management practices alongside protection of forests and permanent pasture from conversion to croplands can be expected to significantly reduce emissions of greenhouse gases from the agriculture and land-use sectors.

Introduction

Previous epidemiologic studies have consistently shown that diet plays a crucial role in the prevention of chronic diseases (Temple, 2000; Willett, 1994). Consumption of fruits and vegetables, as well as grains, has been strongly associated with reduced risk of cardiovascular disease, cancer, diabetes, Alzheimer disease, cataracts, and age-related functional decline (Temple, 2000; Willett, 1994; Willett, 1995). This convincing evidence suggests that a change in dietary behavior such as increasing consumption of fruits, vegetables, and whole grains is a practical strategy for significantly reducing the incidence of chronic diseases (Liu, 2003).

Phytochemicals are the bioactive nonnutrient plant compounds such as the carotenoids, flavonoids, isoflavonoids, and phenolic acids in fruits, vegetables, whole grains, and other plant foods. Thousands of phytochemicals have been identified in foods, yet there are still many that have not been identified. They have been linked to reductions in the risk of major chronic diseases (Liu, 2003). For example, phytochemicals may inhibit cancer cell proliferation, regulate inflammatory and immune response, and protect against lipid oxidation (Hollman and Katan, 1997; Liu, 2003). A major role of the phytochemicals is the protection against oxidation (Boyer and Liu, 2004).

Cells in humans and other organisms are constantly exposed to a variety of oxidizing agents, some of which are necessary for life. These agents may be present in air, food, and water, or they may be produced by metabolic activities within cells. The key factor is to maintain a balance between oxidants and antioxidants to sustain optimal physiologic conditions in the body. Overproduction of oxidants can cause an imbalance, leading to oxidative stress (Liu and Hotchkiss, 1995). Oxidative stress can cause oxidative damage to large biomolecules such as proteins, DNA, and lipids, resulting in an increased risk of cancer and cardiovascular disease (Ames and Gold, 1991; Ames *et al.*, 1993).

Humans, and all animals, have complex antioxidant defense systems, but they are not perfect and oxidative damage will occur. To prevent or slow down the oxidative stress induced by free radicals, sufficient amounts of antioxidants need to be consumed (Ames *et al.*, 1993; Boyer and Liu, 2004). Because prevention is a more effective strategy than treatment for chronic diseases, a constant supply of phytochemical-containing foods with desirable health benefits beyond basic nutrition is essential to furnish the defensive mechanism to reduce the risk of chronic diseases in humans (Liu, 2004). Recent research has also shown that, through overlapping or complementary effects, the complex mixture of phytochemicals in fruits and vegetables provides a better protective effect on health than single phytochemicals (Eberhardt *et al.*, 2000; Liu, 2004). This perspective has been strengthened by the occurrence of inconsistent results in human clinical trials using single antioxidants.

Antioxidant research has been expanded dramatically since the mid-1990s with the development of several assays measuring the total antioxidant activity of pure compounds, foods, and dietary supplements (Cao *et al.*, 1993; Cao *et al.*, 1995; Ou *et al.*, 2001; Prior *et al.*, 2003).

Several assays, such as the trolox equivalent antioxidant activity (TEAC) and oxygen radical absorbance capacity (ORAC) assays, as well as 2,2-diphenylpicrylhydrazyl (DPPH) scavenging and ferric reducing antioxidant power (FRAP) are commonly used to study the antioxidant activities *in vitro* (Arts *et al.*, 2004; Prior *et al.*, 2005; Sharma *et al.*, 2007; Huang *et al.*, 2005). These assays provide a relative measure of antioxidant activity, but often the radicals scavenged have little relevance to those present in biological systems (Perron and Brumaghim, 2009).

However, these total antioxidant activity assays in test tubes do not necessarily reflect the cellular physiological conditions

and do not consider the bioavailability and metabolism issues. In addition, the mechanisms of action of antioxidants go beyond the antioxidant activity of scavenging free radicals in disease prevention and health promotion (Liu, 2004). Animal models and human studies are expensive and not suitable for the initial antioxidant screening of foods and dietary supplements. The best solution is the cell culture models, which support antioxidant research prior to animal studies and human clinical trials (Liu and Finley, 2005). These models provide an approach that is cost-effective, relatively fast, and address some issues of uptake, distribution, and metabolism (Wolfe and Liu, 2007).

The objective of this article is to review the current literature for analyses of antioxidants and antioxidant activities, including assays for total phenolics, total flavonoids, and total antioxidant activities.

Analysis of Total Phenolics in Foods and Dietary Supplements

Phenolic Compounds

Phenolic compounds are compounds that have one or more hydroxyl groups on the aromatic skeleton. Phenols represent group of compounds that have more than one phenolic hydroxyl group attached to one or more benzene rings (Liu, 2004; Dobes *et al.*, 2013; Khoddami *et al.*, 2013; Khatiwora *et al.*, 2010; Ng, 2009).

Phenolics are the products of secondary metabolism in plants, providing essential functions in the reproduction and the growth of the plants; acting as defense mechanisms against pathogens, parasites, and predators; as well as contributing to the color of plants. In addition to their roles in plants, they have been reported to have multiple biological effects, including antioxidant activity, to prevent heart disease, reduce inflammation, lower the incidence of cancers and diabetes, as well as to reduce rates of mutagenesis in human cells (Liu, 2004; Khoddami *et al.*, 2013; Khatiwora *et al.*, 2010).

These compounds may be classified into different groups as a function of the number of phenol rings that they contain and of the structural elements that bind these rings to one another (Liu, 2004). Distinctions are thus made between the phenolic acids, flavonoids, stilbenes, and lignans. The flavonoids, which share a common structure consisting of 2 aromatic rings (A and B) that are bound together by 3 carbon atoms that form an oxygenated heterocycle (ring C), may themselves be divided into 6 subclasses as a function of the type of heterocycle involved: flavonols, flavones, isoflavones, flavanones, anthocyanidins, and flavanols (catechins and proanthocyanidins). In addition to this diversity, polyphenols may be associated with various carbohydrates and organic acids, and with one another (Manach *et al.*, 2004).

Phenolics are widely distributed in plants, spices, vegetables, fruits, whole grains, green and black teas, coffee, fruit juices, olive oil, red and white wines, and chocolates (Perron and Brumaghim, 2009); and are found in medium to high milligram quantities per serving for all of these foods, although measurements of the precise concentrations of phenolic compounds in each type of food often vary. Thus, people with diets rich in fruits and vegetables may consume one or more grams per day of these compounds, based on the recommendation of 5 servings per day of colorful fruits and vegetables by the Centers for Disease Control and Prevention (Perron and Brumaghim, 2009; Gardner *et al.*, 2007; Vison, 1998; Nardini *et al.*, 2002; Vinson *et al.*, 2001; Mertens-Talcott *et al.*, 2006; Seeram *et al.*, 2008; Garcia-Alonso, *et al.*, 2007; Gil *et al.*, 2000; Oboh and Rocha, 2007; Gutierrez *et al.*, 2001; Visioli *et al.*, 1998; Makris *et al.*, 2003; Vinson *et al.*, 1999).

Fruits, vegetables, and beverages such as tea and red wine constitute the main sources of dietary phenolics. Certain phenolics such as quercetine are found in all plant products (fruits, vegetables, cereals, leguminous plants, fruit juices, tea, wine, infusions, etc.), whereas others are specific to particular foods (flavanones in citrus fruit, isoflavones in soya, and phloridzin in apples). In most cases, foods contain complex mixtures of phenolics, which are often poorly characterized (Manach *et al.*, 2004).

Folin–Ciocalteu Assay

The Folin–Ciocalteu (F–C) assay is one of the most popular assays for phenolic analysis (Singleton and Rossi, 1965; Singleton *et al.*, 1999). The principle of the F–C assay is the reduction of the Folin–Ciocalteu reagent (FCR) in the presence of phenolics resulting in the production of molybdenum–tungsten blue that is measured spectrophotometrically at 760 nm and the intensity increases linearly with the concentration of phenolics in the reaction medium as described by Swain and Hillis (1959).

The FCR (Folin and Ciocalteu, 1927) provides an improvement over the Folin–Denis reagent with the addition of lithium sulfate to the reagent. The lithium salts reduce the amount of precipitate that can form when high concentrations of reagent are used to increase the assay's reactivity.

The F–C assay is simple and widely used to determine total phenolics in fruits and vegetables (Chu *et al.*, 2002; Dewanto *et al.*, 2002a,b; Sun *et al.*, 2002; Vinson *et al.*, 2001; Wolfe *et al.*, 2003; Liu *et al.*, 2005; Sun and Liu, 2006).

The common protocol is performed according to Singleton *et al.* (1999) with some modifications according to Dewanto *et al.* (2002a,b). Volumes of 0.5 ml of deionized water and 0.125 ml of diluted fruit extracts were added to a test tube. FCR (0.125 ml) was added to the solution and allowed to react for 6 min. Then, 1.25 ml of 7% sodium carbonate solution was aliquoted into the test tubes, and the mixture was diluted to 3 ml with deionized water. The color was developed after 90 min, and the absorbance was read at 760 nm.

Advantages and Limitations

The F–C method has the advantages of being easy, quickly, and highly reproducible (with a lower coefficient of variation); highly used as screening method for fruits, vegetables, whole grains, and plants.

The F–C assay has a limitation. The reagents for this method do not react specifically with only phenolics but also react with other oxidizable compounds like ascorbic acid, aromatic amines, reducing sugars, and aromatic amino acids (Khoddami *et al.*, 2013; Hatch *et al.*, 1993).

The presence of proteins also interferes in the assay. As a solution for this problem, Hatch *et al.* (1993) proposed using acetone–trichloroacetic acid solution that precipitates proteins.

Yates and Peckol (1993) described the use of polyvinytpolypyrrolidone (PVPP) to alleviating this interference. Phenolic compounds bind to nonsoluble PVPP under acidic conditions and can then be removed from solution by filtering or centrifuging. The remaining oxidizable species are then quantified with a Folin–Ciocalteu or Folin–Denis assay and subtracted from the results of the assay before the addition of PVPP. However, if all the phenolics are not removed by the PVPP, phenolic concentrations are underestimated.

Analysis of Total Flavonoids

Flavonoid Compounds

Flavonoids have a 15-carbon skeleton, which consist of 2 aromatic rings (A and B rings) linked by 3 carbons that are usually in an oxygenated heterocyclic ring, or C ring. Differences in the generic structure of the heterocyclic C ring lead to their classification as flavones, flavonols, flavonones, flavononols, isoflavonoids, flavanols (catechins), and anthocyanidins (Liu, 2004). Flavonols (quercetin, kaempferol, and myricetin), flavones (luteolin and apigenin), flavanols (catechin, epicatechin, epigallocatechin, epicatechin gallate, and epigallocatechin gallate), flavonones (hesperetin and naringenin), anthocyanidins, and isoflavonoids (genistein and biochanin A) are common flavonoids found in the human diet. Flavonoids are most frequently found in nature as conjugates in glycosylated or esterified forms but can occur as aglycones, especially as a result of food processing. These compounds are a class of plant secondary metabolites derived from the condensation of cinnamic acid with three malonyl-CoA groups. (Khoddami *et al.*, 2013; Liu, 2004; Hollman and Arts, 2000).

Flavonoids are the most common group of phenolic compounds that are found ubiquitously in plants (Khatiwora *et al.*, 2010; Ng, 2009), fruits, vegetables, whole grains, bark, roots, stems, flowers, tea, and wine (Liu, 2004; Nijveldt *et al.*, 2001). The concentration of total flavonoids for some samples were described by He *et al.* (2008), blueberry showed the total flavonoid content of 689.5 ± 10.7 mg of quercetin equivalent per 100 g of sample, cranberry 341.5 ± 23.4 mg per 100 g, apple 170.5 ± 7.9 mg per 100 g, broccoli 116.5 ± 8.2 mg per 100 g, and red pepper 73.2 ± 1.9 mg per 100 g.

Flavonoids play an important role in human health (Liu, 2004). They have been reported to have many health benefits including antioxidant activity, antiinflammation, antibacterial and antiviral effects, antiallergenic reaction, and antimutagenic and anticancer properties (Liu, 2004; Liu, 2003; Hanasaki *et al.*, 1994; Hertog and Hollman, 1996; Hertog *et al.*, 1994; Hertog *et al.*, 1993).

Methods Description

The total flavonoids method can be used in fruits, vegetables, whole grains, dietary supplements, and nutraceutical products. First, the quantitative methods of flavonoids were based on the colorimetric F–C assay (Singleton *et al.*, 1999; Singleton and Rossi, 1965), high performance liquid chromatography (HPLC) method (Vaya and Mahmood, 2006; Bloor, 2001), and $AlCl_3$ colorimetric test, but now the most used method to quantify the total flavonoids is the sodium borohydride/chloranil (SBC) assay (He *et al.*, 2008).

The F–C assay is commonly used to quantify the total phenolics. However, this method is not specific to flavonoids because it detects compounds with active hydroxyl group(s) including phenolic acids, flavonoids, ascorbic acid, reducing sugars, some amino acids, and aromatic amines (He *et al.*, 2008).

The usage of HPLC to quantify the flavonoids compounds is specific and sensitive. However, the problem with this method is the numbers of pure standard compounds available and the separation capacity of the HPLC column. In addition, there are more than 4000 flavonoids that have been identified, but a large percentage of them remain unknown (Liu, 2004). Therefore, it is not a good option to choose HPLC method to quantify the total flavonoid compounds.

The general technique mostly employed previously for quantification of flavonoids is based on the spectrophotometric determination of complex flavonoid–$AlCl_3$, which provides a bathochromic displacement and the hyperchromic effect (Mabry *et al.*, 1970). Although, there are some analytic limitations on this method described by Christ and Muller (1960), one of the problems of this method is when the total flavonoids are quantified in the fruits and vegetables, because some flavonoids containing C-glycosides do not undergo acid hydrolysis, and they are discarded in the aqueous phase during the liquid–liquid extraction due to the polarity from glucosyl residue (Ortega and Silva, 2001). Other factors have been revealed as crucial during the formation of the flavonoid–$AlCl_3$ complexes such as: the reaction time, the concentration of the reagent ($AlCl_3$ and flavonoid content/plant materials), and the chemical structure of the phenolic (Ortega and Silva, 2001). The $AlCl_3$ colorimetric test for flavonoids does not measure those flavonoids that do not bear the characteristic chelating functional groups for Al binding. Essentially flavones (e.g., chrysin, apigenin, luteolin, etc.) and flavonols (e.g., quercetin, myricetin, morin, rutin, etc.) react with Al(III), whereas flavanones and flavanonols do not form complex to the same extent (Chang *et al.*, 2002).

The SBC assay was developed in the lab and it has been used by many scientists to quantify the total flavonoids (He *et al.*, 2008). This method has the advantage of detecting all types of flavonoids, including flavones, flavonols, flavonones, flavononols, isoflavonoids, flavanols, and anthocyanins. The flavonoids with a 4-carbonyl group were reduced to flavan-4-ols using sodium borohydride catalyzed by aluminum chloride. Then the flavanols were oxidized to anthocyanins by chloranil in acetic acid solution (He *et al.*, 2008).

The SBC assay is used to quantify total flavonoids content in foods, vegetables, whole grains, herbal products, dietary supplements, functional foods, and nutraceutical products foods to support flavonoid-related health claims and to provide more accurate data for future epidemiological studies and human clinical trials. This assay is accurate, precise, and specific for total flavonoids and is a powerful tool in antioxidant research (He *et al.*, 2008).

The principle of the SBC method to quantify total flavonoids content is: flavonoids with a 4-carbonyl group (flavones, flavonols, flavonones, flavononols, and isoflavonoids) were reduced to flavan-4-ols (catechins) using sodium borohydride (Sweeny and Iacobucci, 1977a). This reaction was catalyzed by the addition of aluminum chloride to achieve a high yield of flavan-4-ols. The flavanols (catechins) were oxidized to anthocyanins by chloranil in acetic acid solution (Sweeny and Iacobucci, 1977b; Sweeny and Iacobucci, 1981; Jurd, 1966). The anthocyanins generated in the reaction were quantified spectrophotometrically at 490 nm after the addition of vanillin and concentrated hydrochloric acid (Sarkar and Howarth, 1976; Broadhurst and Jones, 1978).

The protocol for total flavonoids test is performed according to the method described by He *et al.* (2008). Briefly, 4 ml extracts of tested samples were added into test tubes, then dried to dryness under nitrogen gas, and reconstituted in 1 ml of THF/EtOH (1:1, v/v). Catechin standards (0.1–8.0 mM) were prepared fresh each day before use in 1 ml of THF/EtOH (1:1, v/v). To each test tube with 1 ml of sample solution or 1 ml of catechin standard solution, 0.5 ml of 50 mM NaBH4 solution and 0.5 ml of 74.56 mM $AlCl_3$ solution were added. The mixture was shaken in an orbital shaker at room temperature for 30 min. Then an additional 0.5 ml of $NaBH_4$ solution was added into each test tube with continuing shaking for another 30 min at room temperature. Cold acetic acid solution (2.0 ml of 0.8 M, 4 °C) was added into each test tube, and the solutions were kept in the dark for 15 min after a thorough mix. Then, chloranil (1.0 ml, 20 mM) was added into each tube, which was heated at 100 °C with shaking for 60 min in a reciprocal shaking bath. The reaction solutions were cooled using tap water, and the final volume was brought to 4 ml using methanol. Then, 1 ml of 1052 mM vanillin was added into each tube, followed by mixing. Concentrated HCl (2.0 ml, 12 M) was added into each tube, and the reaction solutions were kept in the dark for 15 min after a thorough mix. Aliquots of the final reaction solutions (200 µl) were added into each well of a 96-well plate, and absorbances were measured at 490 nm.

Chemical Total Antioxidant Activity Assays

Techniques that measure total antioxidant activities of foods can be valuable in studying the relationship between dietary factors and chronic disease prevention, as well as providing vital information for selecting good dietary sources of antioxidants. This has led to the development of diverse new or improved methods applied to all kinds of plant-based foods (Ou *et al.*, 2001; Ou *et al.*, 2002; Pulido *et al.*, 2000; Naguib, 2000; Arnao *et al.*, 2001; Aldini *et al.*, 2001; Huang *et al.*, 2002).

Over 20 methods are used for assessment of antioxidant capacities (Frankel and Meyer, 2000). The significance of the measured values and mutual comparison of the results gained by individual method is still an unresolved problem.

The measurement of antioxidant activity is an important screening method to compare the oxidation/reduction potentials of fruits and vegetables and their phytochemicals in various systems. Many chemistry methods are currently in wide use, including the ORAC (Cao *et al.*, 1993), total radical-trapping antioxidant parameter (TRAP) (Ghiselli *et al.*, 1995; Wayner *et al.*, 1985), TEAC (Miller *et al.*, 1993), total oxyradical scavenging capacity (TOSC) (Winston *et al.*, 1998), and the peroxyl radical scavenging capacity (PSC) assays, the latter of which was developed by our laboratory (Adom and Liu, 2005). FRAP assay (Benzie and Strain, 1996) and the DPPH free radical method (Brand-Williams *et al.*, 1995) measure the ability of antioxidants to reduce ferric iron and DPPH, respectively.

For the methods based on similar principles of electron transfer (ET), there are the TEAC, FRAP, and DPPH. For the hydrogen atom transfer methods (HAT), there are the ORAC method, TRAP, TOSC, and the PSC assays (Stratil *et al.*, 2007; Badarinath *et al.*, 2010).

Ferric Reducing Antioxidant Power Assay

This is a colorimetric assay that measures the ability of plasma to reduce the intense blue ferric tripyridyltriazine complex to its ferrous form, thereby changing its absorbance (Benzie and Strain, 1999).

The advantages of this method are simple, speedy, and inexpensive, and do not required specialized equipment. It can be performed using automated, semiautomated, or manual methods (Benzie and Strain, 1999). But the disadvantages are that FRAP cannot detect species that act by radical quenching (H transfer), particularly SH group containing antioxidants like thiols, such as glutathione and proteins (Prior and Cao, 2000; Huang *et al.*, 2005; Cao and Prior, 1998).

The FRAP assay was done according to Benzie and Strain (1996) with some modifications. The stock solutions included 300 mM acetate buffer (3.1 g $C_2H_3NaO_2 \cdot 3\ H_2O$ and 16 ml $C_2H_4O_2$), pH 3.6, 10 mM TPTZ (2,4,6-tripyridyl-s-triazine) solution in 40 mM HCl, and 20 mM $FeCl_3 \cdot 6\ H_2O$ solution. The fresh working solution was prepared by mixing 25 ml acetate buffer, 2.5 ml TPTZ solution, and 2.5 ml $FeCl_3 \cdot 6\ H_2O$ solution and then warmed at 37 °C before use. Fruit or vegetable extracts (150 ml) were allowed to react with 2850 ml of the FRAP solution for 30 min in the dark condition. Readings of the colored product (ferrous tripyridyltriazine complex) were then taken at 593 nm. The standard curve was linear between 25 and 800 mM Trolox. Results are expressed in mM Trolox equivalents (TE) per gram fresh mass.

Trolox Equivalent Antioxidant Capacity

This assay is based on the ability of molecules to scavenge the stable free radical of 2,2′-azinobis-(3-ethylbenzothiazoline-6 sulfonic acid)(ABTS) in comparison with Trolox, a water-soluble analog of vitamin E. The activity of a compound is, therefore, expressed as TEAC units. This technique has not been widely applied, which limits the possibility to compare results from different studies. All the other assays have been applied in plasma reproducibility (Badarinath *et al.*, 2010).

For TEAC or ABTS assay, the procedure followed the method of Arnao *et al.* (2001) with some modifications. The stock solutions included 7.4 mM $ABTS^+$ solution and 2.6 mM potassium persulfate solution. The working solution was then

prepared by mixing the two stock solutions in equal quantities and allowing them to react for 12 h at room temperature in the dark. The solution was then diluted by mixing 1 ml $ABTS^+$ solution with 60 ml methanol to obtain an absorbance of 1.1 ± 0.02 units at 734 nm using the spectrophotometer. Fresh $ABTS^+$ solution was prepared for each assay. The extracts (150 ml) were allowed to react with 2850 ml of the $ABTS^+$ solution for 2 h in a dark condition. Then the absorbance was taken at 734 nm using the spectrophotometer. The standard curve was linear between 25 and 600 mM Trolox. Results are expressed in mM TE per gram fresh mass.

2,2-Diphenyl-1-Picrylhydrazyl

DPPH is a stable free radical at room temperature, which produces a violet solution in methanol. When the free radical reacts to an antioxidant, its free radical property is lost due to chain breakage and its color changes to light yellow (Badarinath *et al.*, 2010).

DPPH method was commonly used because it is a very simple, sensitive, and rapid method, which was very convenient for the screening of many samples of different polarity (Koleva *et al.*, 2002).

DPPH protocol was described by Brand-Williams *et al.*, (1995). Ethanolic solutions in different concentrations were prepared by adding 1000 µl of DPPH (0.004% w/v), and the final volume was brought to 1200 µl with ethanol. Each tube was incubating for 30 min at room temperature in the dark. The same procedure was taken for gallic acid. The control was prepared as above without any extract, and ethanol was used for the baseline correction. The DPPH solution was freshly prepared daily, stored in a flask covered with aluminum foil, and kept in the dark at 4 °C between measurements. The percent decrease in absorbance was recorded for each concentration and percent quenching of DPPH was calculated on the basis of the observed decrease in absorbance of the radical. Changes in the absorbance of the samples were measured at 517 nm.

Total Oxyradical Scavenging Capacity

Winston *et al.* (1998) developed the TOSC. The substrate that is oxidized in this assay is α-keto-gamma-methiolbutyric acid, which forms ethylene. The time course of ethylene formation is followed by head space analysis of the reaction cell by gas chromatography, and the antioxidant capacity is quantified by the ability of the antioxidant to inhibit ethylene formation relative to a control reaction.

The advantage of the TOSC method is that it permits the quantification of the antioxidant capacity toward three oxidants, that is, hydroxyl radicals, peroxyl radicals, and peroxynitrite (Regoli and Winston, 1999). At the same time, the disadvantage of this method is not readily adaptable for high-throughput analyses required for quality control in that it requires multiple injections from a single sample into a gas chromatograph to measure the production of ethylene (Lichtenthaler and Marx, 2005).

Peroxyl radicals were generated by the thermal homolysis of ABAP at 35 and 39 °C. Reactions were carried out in 10 ml rubber septum-sealed vials in a final volume of 1 ml. The reactions were initiated by injection of 100 ml of 200 mM ABAP in water directly through the rubber septum. Ethylene production was measured by gas-chromatographic analysis of 1 ml aliquots taken directly from the head space of the reaction vials. By staggering the starting times for each vial, 8–10 serial samples can be monitored in sequence at 12-min intervals. Analyses were performed with a gas chromatograph equipped with a flame ionization detector.

Measurement of Oxygen Radical Scavenging Capacity

ORAC assay is an HAT assay first developed by Cao *et al.* (1993) to measure total antioxidant capacity of secondary antioxidants. The assay is based on the fluorescence method for peroxy radicals developed by DeLange and Glaze in 1989. ORAC assay has been one of the most commonly used antioxidant activity assays in research and food industries (Caldwell, 2001). But the disadvantage is that it requires fluorometers, which may not be routinely available in analytical laboratories. Temperature control decreases reproducibility (Badarinath *et al.*, 2010).

The protocol for ORAC method is performed according to Prior *et al.*, 2003. Briefly, 20 µl of blank, Trolox standard, or food extracts in 75 mM potassium phosphate buffer, pH 7.4, was added to triplicate wells in a black, clear-bottom, and 96-well microplate. The triplicate samples were distributed throughout the microplate and were not placed side by side, to avoid any effects on readings due to location. A volume of 200 µl of 0.96 µM fluorescein in working buffer was added to each well and incubated at 37 °C for 20 min, with intermittent shaking, before the addition of 20 µl of freshly prepared 119 mM ABAP. The microplate was immediately inserted into a plate reader at 37 °C. The decay of fluorescence at 538 nm was measured with excitation at 485 nm every 5 min for 2.5 h. The areas under the fluorescence versus time curve for the samples minus the area under the curve for the blank were calculated and compared to a standard curve of the areas under the curve for 6.25, 12.5, 25, and 50 µM Trolox standards minus the area under the curve for blank.

Rapid Peroxyl Radical Scavenging Capacity

PSC method is a rapid, simple, and reliable approach for measuring both hydrophilic and lipophilic antioxidant capacity of pure antioxidant compounds, food extracts, and biological fluids toward biologically relevant radicals, based on the oxidation of 2′,7′-dichlorofluorescin (DCFH) by peroxyl radicals (Adom and Liu, 2005).

The reaction mechanism for PSC assay is as follows: Thermal degradation of ABAP produces peroxyl radicals (ROOH) (Pryor *et al.*, 1993; Winston *et al.*, 1998), which oxidize nonfluorescent DCFH to fluorescent dichlorofluorescein (DCF). The degree of inhibition of DCFH oxidation, by antioxidants that scavenge peroxyl radicals, was used as the basis for calculating antioxidant activity.

The protocol for PSC method is performed according to the method of Adom and Liu (2005). Just before use in the reaction, 80 µl of 2.48 mM DCFH-DA was hydrolyzed with

900 µl of 1.0 mM KOH for 3–5 min in a vial to remove the diacetate (DA) moiety and then diluted to 6 ml total volume with 75 mM phosphate buffer (pH 7.4). DCFH-DA was stable to oxidation, whereas DCFH was very slowly oxidized at ambient conditions without ABAP. ABAP (200 mM) was prepared fresh in buffer, and each batch was kept at 4 °C between runs. In a run, 100 µl of pure compounds or food extracts appropriately diluted in 75 mM phosphate buffer (pH 7.4) was transferred into reaction cells on a 96-well plate, and 100 µl of DCFH was added. The 96-well plate was loaded into the plate reader and the solution in each cell was mixed by shaking at 1200 rpm for 20 s. The reaction was then initiated by adding 50 µl of ABAP. The reaction was carried out at 37 °C, and fluorescence was monitored at 485 nm excitation and 538 nm emission with the fluorescent spectrophotometer. The buffer was used for control reactions. Reaction conditions were all optimized from preliminary studies for the control reaction to be completed (to reach maximum fluorescence) in 40 min.

Using randomly methylated α-cyclodextrin (RMCD) simplifies the preparations steps and most importantly ensures enhanced solubility of lipophilic compounds without any interfering side reactions, because RMCD is chemically inert in this reaction. Use of both hydro-PSC and lipo-PSC assays extends the applicability of this method to include both hydrophilic and lipophilic antioxidant capacities of foods. Results from such analyses should give more complete information on the antioxidant protection offered by a large diversity of foods (Adom and Liu, 2005).

Special Considerations for Chemical Total Antioxidant Activity Assays

Most of the data presented in the literature have been on antioxidant activities of water-soluble food extracts. Of additional interest, however, is the antioxidant activity of lipid-soluble components of foods, which are becoming very important in combating specific types of radicals and diseases. Lipophilic antioxidants play unique roles in the body (Bernstein *et al.*, 2001; Snodderly, 1995; Beatty *et al.*, 2000; Landrum and Bone, 2001; Burton and Ingold, 1986). Therefore, measurement of their contributions to the total antioxidant activity of foods can assist in elucidating the role these compounds play in disease prevention and health promotion. Information on total antioxidant capacity (both lipophilic and hydrophilic) would therefore give a more complete spectrum of protection provided by foods and their contribution toward disease prevention.

Most current antioxidant capacity assays are performed in aqueous solutions and are not suitable for lipophilic antioxidant capacity measurements. Another major improvement in measuring antioxidant capacity has been the introduction of fluorescein dyes as fluorescent probes for monitoring the reaction (Huang *et al.*, 2002; Ou *et al.*, 2002). Incorporation of fluorescent probes and cyclodextrin into antioxidant capacity assays have extended the application and usefulness of data generated from such experiments. For example, the methods of Ou *et al.* (2001) and Huang *et al.* (2002) were recently adopted by Wu *et al.* (2004) to measure the hydrophilic and lipophilic antioxidant capacities of over 100 common foods in the US market.

The PSC assay generates results comparable to similar more modern assays using fluorescein derivatives as probes and may even have certain additional advantages. For instance, with the hydroxyl radical averting capacity (HORAC) assay, it was observed that the intercept of the linear standard curves keep changing with each run, suggesting that, to eliminate the uncertainty of the intercept, it may be necessary to obtain standard curves within the run to compute final values (Ou *et al.*, 2002). The PSC assay does not require a linear standard curve, and for practical purposes using a concentration range that includes the EC_{50} produces accurate and reproducible results. The PSC assay is also very sensitive, being able to run in the low micromolar range. Adapting the PSC assay to run in a 96-well plate and also using a fluorescent dye allows the assay to be performed on simple fluorescent spectrophotometers. The method can be easily automated as has been done for the ORAC assay (Huang *et al.*, 2002).

Among all methods described in the literature for determining the antioxidant potential *in vitro*, the ORAC and PSC methods are commonly used because of the physiological relevant radicals. The PSC method has lower variation due to the incorporation of the fluorescence probe DCFH allowing for less interference, and can be used to evaluate the effects of processing and storage on antioxidant activities of fruits, vegetables, and food products (Adom and Liu, 2005).

Limitations of Chemical Antioxidant Activity Assays

Despite wide usage of these chemical antioxidant activity assays, their ability to predict *in vivo* activity is questioned for a number of reasons. Some are performed at nonphysiological pH and temperature, and none of them take into account the bioavailability, uptake, and metabolism of the antioxidant compounds (Liu and Finley, 2005). The protocols often do not include the appropriate biological substrates to be protected, relevant types of oxidants encountered, or the partitioning of compounds between the water and lipid phases and the influence of interfacial behavior (Frankel and Meyer, 2000).

Bioavailability and metabolism are two important questions that need to be addressed in the study of the biological effects of antioxidants (phytochemicals) in foods. The form of antioxidants found in foods is not necessarily the same as the form found in the blood or the targeted tissues after digestion, absorption, and metabolism. To study the mechanisms of action of antioxidants in the prevention of chronic disease, two important questions to be asked are the following: Are these antioxidants (phytochemicals) bioavailable? Are these original antioxidants or their metabolites the bioactive compounds? It is crucial to understand the bioavailability and metabolism of these compounds to gain knowledge of what compounds and how much of these compounds actually reach target tissues. In some cases, the original phytochemicals may be excreted or metabolized and never actually reach target tissue, and the active compounds may not be the original antioxidant compounds found in foods but rather their metabolites. Till date, many studies did not address the bioavailability and metabolism of phytochemicals from whole foods (Liu and Finley, 2005; Wolfe and Liu, 2007).

Examining the bioavailability of compounds from food sources can be challenging, because there are many factors that may influence bioavailability. Foods contain a wide variety of phytochemicals, and interactions with other chemicals in the food may affect bioavailability. Phytochemicals may be bound to different sugars (glucosides, xylosides, rhamnosides, or galactosides) or to other compounds (fibers) that may affect the compound's bioavailability. Other factors, such as digestion, food processing, and stage of harvest, may also affect phytochemical bioavailability. Although much progress has been made in understanding the bioavailability and further metabolism of pure compounds, more work is needed to further comprehend the bioavailability of phytochemicals from complex food sources (Liu and Finley, 2005).

A good *in vitro* model would be beneficial in this area of study in evaluating the bioavailability of phytochemicals from foods by offering a simple method to screen for factors that may affect intestinal absorption of phytochemicals, such as the food matrix, food processing, digestion, and interactions with other foods. Human and animal models can be expensive and time-consuming, whereas a cell culture model allows for rapid, inexpensive screenings. The Caco-2 cell culture model has the potential to be a good model to measure the bioavailability of antioxidants, such as carotenoids and flavonoids, from whole foods (Liu *et al.*, 2004; Boyer *et al.*, 2004; Boyer *et al.*, 2005; Garrett *et al.*, 1999; Deprez *et al.* 2001).

Popular antioxidant activity/capacity assays, such as ORAC (Cao *et al.*, 1993), TRAP (Ghiselli *et al.*, 1995), TEAC (Miller *et al.*, 1993), TOSC (Winston *et al.*, 1998), PSC (Adom and Liu, 2005), and FRAP (Benzie and Strain, 1996), all have the limitation of the inability to represent the complexity of biological systems. They measure chemical reactions only, and these reactions cannot be interpreted to represent activity *in vivo*, as they cannot account for the bioavailability, stability, tissue retention, or reactivity of the compounds under physiological conditions (Huang *et al.*, 2005).

The importance of using a more biologically relevant model in the determination of antioxidant activity is highlighted by the differences between the results of pure chemistry assays and those based in cell culture.

Cell-Based Total Antioxidant Assay

Biological systems are much more complex than the simple chemical mixtures employed, and antioxidant compounds may operate through multiple mechanisms (Liu, 2004). The different efficacies of compounds in the various assays attest to the functional variation. The best measures are from animal models and human studies; however, these are expensive, time-consuming, not suitable for initial antioxidant screening of foods and dietary supplements (Liu and Finley, 2005).

Cell culture models provide an approach that is cost-effective, relatively fast, and address some issues of uptake, distribution, and metabolism. Wolfe and Liu (2007) developed a cell-based antioxidant activity assay to screen foods, phytochemicals, and dietary supplements for potential biological activity. This method named cellular antioxidant activity (CAA). It was developed in the response to a need for a more biologically representative method than the chemistry antioxidant activity assays commonly used to screen antioxidant materials for potential biological activity (Wolfe and Liu, 2007).

It has been suggested that the following should be considered in choosing appropriate methods to measure antioxidant activity: physiologically relevant substrates; conditions that mimic biological systems; low levels of oxidants that represent all stages of oxidation; measurement of different compounds at comparable concentrations and use of plant extracts where the phenolic composition is known; and quantification based on induction period, percent inhibition, rates of product formation/decomposition, or median effective dose (Frankel and Meyer, 2000).

In CAA method, the probe, DCFH-DA, is taken up by HepG2 human hepatocarcinoma cells and deacetylated to DCFH. Peroxyl radicals generated from ABAP lead to the oxidation of DCFH to fluorescent DCF, and the level of fluorescence measured upon excitation is proportional to the level of oxidation. Pure phytochemical compounds and food extracts quench peroxyl radicals and inhibit the generation of DCF. Thus, the CAA assay uses the ability of peroxyl radicals, reactive products of lipid oxidation, to induce the formation of a fluorescent oxidative stress indicator in the cell culture and measures the prevention of oxidation by antioxidants (Wolfe and Liu, 2007).

The protocol for CAA method is performed according to the method described by Wolfe and Liu (2007). Briefly, human hepatocellular carcinoma HepG2 cells were seeded at a density of 6×10^4 per well on a 96-well microplate in 100 µl of growth medium/well. Twenty-four hours after seeding, the growth medium was removed, and the wells were washed with PBS. Wells were treated in triplicate for 1 h with 100 µl of treatment medium containing tested fruit extracts plus 25 µM DCFH-DA. Then 600 µM ABAP was applied to the cells in 100 µl of HBSS, and the 96- well microplate was placed into a plate reader at 37 °C. Emission at 538 nm was measured after excitation at 485 nm every 5 min for 1 h. Each plate included triplicate control and blank wells. Control wells contained cells treated with DCFH-DA and ABAP. Blank wells contained cells treated with DCFH-DA and HBSS. Results were expressed as µmol quercetin equivalents (QE) per 100 g of fresh fruit.

Conclusions

Increased consumption of fruits, vegetables, whole grains, and other plant-based foods has been linked to the reduced risk of developing chronic diseases. Public interest in dietary antioxidants has been increased dramatically, and antioxidant researches have been boosted in recent decades. Many chemistry-based assays have been developed to measure the antioxidants and total antioxidant activities in food samples and dietary supplements, such as total phenolic analysis assay and SBC assay, ORAC assay, TRAP assay, TOSC assay, PSC assay, TEAC assay, DPPH assay, and FRAP assay. However, these chemistry-based assays do not reflect the complexity of biological systems and physiological conditions, and do not consider the issues of bioavaibility and metabolisms (Liu and Finley, 2005; Wolfe and Liu, 2007; Wolfe and Liu, 2008). CAA assay is a newly developed antioxidant assay based on a cell

culture model to test antioxidant activities of food samples and dietary supplements *in vitro* and generates test results that are more biologically relevant (Wolfe and Liu, 2007). As the cell-based antioxidant activity assays better take bioavailability and metabolism of antioxidants into consideration at the physiological conditions, they open a new field and may lead the direction for future studies in antioxidant research.

Glossary

Anorexia A symptom that reflects the lack of appetite. It could induce weight loss that is considered unhealthy.

Ataxia A nonspecific neurological sign that consists of lack of voluntary coordination of muscle movements. It could be as a result of dysfunction of the cerebellum, the loss of sensitivity to the positions of joint and body parts (proprioception), or to dysfunction of the vestibular system (disequilibrium).

Dyspnea A symptom of breathlessness commonly associated to respiratory distress.

Enzootic Organism that is native to a place or a specific fauna.

Fomite Any object or substance capable of carrying infectious organisms and able to transfer them from one individual to another.

Leucopoenia A condition of a decreased number of leukocytes (commonly referred to as white blood cells) in the blood. It is also known as leukopenia, or leuokopoenia, and is one of the most important indicators of infection risk.

Recombinant DNA vaccine A vaccine that uses viruses or bacteria into which harmless genetic material from disease-causing organisms are inserted using genetic engineering techniques. Recombinant vaccines aim to create a strong antibody and T-cell immune response leading to protection against the targeted disease.

Sylvatic A pathogen or disease that affects only wild animals.

Thrombocytopenia A condition of a decreased number of platelets in the blood.

Transhumance The seasonal movement of people with their livestock. It is also known as nomadic movement.

Introduction

Ectoparasites and vectorborne diseases have a major impact on the productivity and welfare of livestock and wildlife and represent a constant risk for the survival and well-being of major human groups throughout the world (McDermott *et al.*, 1999; Perry and Sones, 2007; Herrero *et al.*, 2010; Thornton, 2010; Gachohi *et al.*, 2011; Rich and Perry, 2011; FAOSTAT, 2012; Grace *et al.*, 2012).

Recent surveys have estimated that the livestock population worldwide has reached 24 billion in 2012 (FAOSTAT, 2012). Analysis of the Food and Agriculture Organization of the United Nations Statistical Program (FAOSTAT) indicates that there are five major groups of livestock with major economical and welfare impact for humans worldwide: cattle/buffaloes, sheep/goats, chickens, swine, and horses (**Table 1**). Cattle and buffaloes with 1.6 billion heads worldwide are mostly concentrated in Asia (32% with more than 520 million animals), followed by South America (20%), Africa (15%), North America (14%), and Europe (10%). Similarly, sheep/goats with more than 2000 million animals worldwide are mainly distributed in Asia (>670 million), Africa (>250 million), and Oceania (>100 million).

Ectoparasites, such as ticks, fleas, biting flies, ked, mites, midges, lice, and mosquitoes, could impose a heavy burden to livestock affecting productivity. Blood loss, irritation, and discomfort could induce damage to the animal skin (hides and wool), reduce milk production, decrease immunity response, and cause retarded growth rates. In addition, ectoparasites represent a constant threat to livestock due to their competence (either as amplifiers or mechanically) for the transmission of a large number of pathogens with high morbidity and mortality implications. In addition to the worldwide economic toll caused by ectoparasites, livestock health has direct implications of sustainability of a large percentage of the world population (Kristjanson *et al.*, 2009). From the more than 6 billion people inhabiting the earth, more than a billion are living in poverty depending partially or totally on livestock (referred to as poor livestock keepers). The subsistence of these groups, most of them concentrated in Asia (600 million), East and West Africa (300 million), and South America (100 million), is constantly jeopardized by many livestock diseases, such as Bluetongue, Anaplasmosis, East Coast fever, babesiosis, Trypanosomiasis, and Rift Valley fever, that have a devastating impact, irrespective of whether they are through animal deaths, through the loss of markets and income, or because of the zoonotic potential on human health.

The increased activities toward intensification of agricultural practices and of livestock production, along the increasingly sale of live animals for food or pets, landscape modification, poor ecosystem protection, and the extensive transportation networks, create host populations conducive to evolution and persistence of parasites and vectors. This has a much greater impact in developing or poor countries of the tropical and subtropical regions, where climatic conditions favor parasite's survival and transmission or where there are the major economical impediments for adequate control of parasites, or where the systems for disease control and reporting are relatively weak (Grace *et al.*, 2011).

Ectoparasites are arthropods organisms that could seriously limit the production on livestock and so lowering the income from milk and meat sales and less access to liquid capital, could serve as potential for several zoonotic diseases, and could threat livelihoods of key household assets. The economic losses due to the direct and indirect consequences of ectoparasites in cattle production in Africa alone are estimated

Table 1 Worldwide distribution of the major livestock species

Region	*Country*	*Livestock*[a] total	*Cattle/buffaloes*	*Sheep/goats*	*Horses*	*Swine*	*Chicken*
Asia	India	559.1	321	228	0.5	9.6	774

between US$1000 and US$1200 million annually (UNEP, 2012), with a total loss of US$4 750 000 year^{-1} in terms of agricultural gross domestic product.

There are four major groups of ectoparasites that affect livestock (Table 2): ticks (responsible for major losses amongst livestock worldwide), biting flies, mites, and lice.

Direct Consequence of Ectoparasites in Livestock

'Discomfort,' induced by intense itching and scratching, could lead to skin and hide damage. If intense enough, it could lead to a decreased productivity (either as a result of reduce feeding or due to erratic behavior) and depreciated value of skins (hides, wool, and leather) or the livestock as commodity. Chicken mites could cause papules on any part of the bird, could be debilitating, and could result in skin irritation, stunted growth, loss of vigor, reduced egg production, anemia, and even death. The cattle follicle or the goat follicle mite could cause lesions on the neck, shoulders, and axillary region of the animal. Papulonodular demodicosis can occur in pregnant or lactating animal where nodules could form over time ranging from a pin head to a chicken egg in size. These nodules can rupture and produce skin damages (sores) that can lead to defects in raw leather and economic losses in the hide industry. The scabies mite could cause adverse effects to the host by depositing feces into the burrows they live in, producing papules, puritus, and hair loss, where the skin may become thickened crusted and where secondary infection occurs. In extreme infestations, sensitive animals may experience weight loss, eating difficulty, hearing impairment, blindness, exhaustion, and death. Similarly, psoroptic ear mite infestation could cause scaling, crusting, inflammation, and hair loss of the ear as well as accumulation of wax, ear scratching, head shaking, and rubbing of the head and ears. Chronic infestations can lead to anemia and weight loss and in extreme cases can be fatal.

Early reports on losses caused by lice in the United States, for example, estimate that lice cause a 68 lb per head weight loss in 12% of the cattle slaughtered, representing an estimated cost of more than US$126 million (Drummond, 1985). The losses in weight gain, hide values, and even those associated with the type of housing, including damage of fences, hay racks, and buildings, due to rubbing are very dependent on variables, such as sex, age, and immunity (Michel *et al.*, 1979; Geden and Stoffolano, 1980; Lancaster *et al.*, 1982; Meyer *et al.*, 1982; Gibney *et al.*, 1985; Lancaster, 1986).

'Anemia' due to blood intake could result in animals with high parasitism. Some examples include mosquitoes that could cause painful bites, loss of weight, and reduction of milk production; sucking lice infestation that could result in loss of weight, poor performance, and reduction of milk production due to blood loss; and the lethargy associated with the dullness, nervousness, and irritation induced by the lice-feeding activity. Ticks that bite may induce inflammation, itching, and swelling and potentially induce secondary infections.

Ticks have a negative impact on cattle as they cause weight loss in animals and decrease the milk production. Some estimates showed that infestation with large number of engorged *Boophilus* female ticks could reduce the annual weight by up to 0.5 kg per animal and decrease the annual milk production by up to 200 l per animal.

Table 2 Major parasite groups, species (scientific and common names) and their impact on the hosts

Parasite	*Species*	*Common name*	*Host*	*Consequences*
Biting flies	*Simulium* spp.	Black flies, buffalo gnat, turkey gnat, or white socks	Cattle, horses, and livestock	Annoyance, tissue damage, blood loss, anaphylactic shock, and death
	Melophagus ovis	Sheep ked	Sheep	Annoyance, leading it to rub, producing both loss and damage of the wool. It also produces hard nodules on the skin (known as cockle) which reduce the value of the hide
	Tabanus spp.	Horse flies, breeze flies, clegs or clags, deer flies, gad flies, stable flies, and zimbs	Horse, cattle, and other livestock	They are vicious painful biters that feed on blood during daytime interfering with the animal behavior. They could induce poor performance in animals, and a decrease in weight gain and milk production. Infection may also predispose animals to secondary infections if present in large numbers
	Haematobia irritans	Horne fly	Cattle, horses, sheep, and goats	Annoyance, blood loss, reduction in milk production, growth rate, and weight gain. Could induce also secondary infections, including myiasis by other flies species
	Oestrus ovis	Sheep bot flies	Sheep, deer, goat, cattle, and horses	Annoyance and discomfort, leading to reducing grazing lose weight and in some cases death. The area most affected by larvae deposition is the nose, causing irritation to the mucosa, swelling of the internal membranes of the nose, possibly impairment of breathing. In extreme infections, it could cause septic sinusitis and the possibility of death from general septicemia
	Hypoderma spp.	Warble fly, heel flies, bomb flies, or gad flies	Cattle and deer	Typically the laid eggs are deposited on the foreleg and are ingested by licking. After an internal cycle involving the passing through the esophagus muscles and spinal cord, the larvae reemerge, causing subcutaneous swellings ('warbles') and skin damage (holes) reducing the skin value. If the infestation is severe, the injure on the tissues due to the migrating larvae, may seriously slow growth rate, decrease milk production and weight gain, and so reduce the profitability of livestock production on both meat or hide.
	Gasterophilus spp.	Horse bot flies	Horses, caribou, and donkeys	Larvae from eggs laid around the mouth, eyes, nose, and chin (by *Gasterophilus nasalis*) travel to the sinus cavities or the brain. Fly eggs laid or around the lower legs and shoulders (by *Gasterophilus intestinalis*) hatch by licking and travel to the mouth and into the intestines. The larvae affect the animal by interfering with feeding, causing stomach lesions that can become a site of secondary infection and by causing restlessness when the larvae are in the rectum before passage. Horses with large numbers of bots become run down and unthrifty.
	Cochliomyia hominivorax	Screw-worm fly	Cattle, sheep, and other livestock	Parasitic fly whose larvae (maggots) eat the living tissue. Fly lays eggs on wounded tissues (as a consequence of barbed wire cuts, flea bites, branding, castrating, dehorning, or tailing of the host animal) and after hatching, larvae will burrow deeper perpendicular to the skin surface eating into live flesh
	Cuccoides spp. and *Leptoconops* spp.	Sand flies, biting midges, noseeums, and punkies	Cattle, sheep, and deer	Annoyance and blood loss. They could also induce suffocation, if present in large numbers

(*Continued*)

Table 2 Continued

Parasite	*Species*	*Common name*	*Host*	*Consequences*
	Hippobosca spp.	Forest fly,	Sheep, goats, red deer, camels, and rabbits	Annoyance and blood loss
Ticks	*Ornithodoros* spp. and *Otobius* spp.	Soft tick	Swine, cattle, sheep, antelope, deer, camels, and poultry birds	Annoyance and blood loss
	Hyalomma spp., *Ixodes* spp., *Dermacentor* spp., *Amblyomma* spp., *Boophilus* spp., and *Rhipicephalus* spp.	Hard tick	Cattle, sheep, deer, and goat	Even in general not painful, hard tick bites could cause inflammation at the wound, followed by acquired immune reactions in the skin. Biting stress could cause lameness, anorexia (loss of appetite), blood loss, and reduced weight gain and milk production. Damage to the skin and hide due to the scar may remains for years reducing the value of the leather. Some species may also induce some toxic effects on the host (such as eczema, alopecia, fever, or paralysis)
Lice	*Damalinia* spp.	Cattle biting louse	Cattle, sheep, goats, and horses	Annoyance, interfering with normal animal behavior and decreasing weight gain and milk. Large numbers cause intense pruritis and irritation and chronic dermatitis due to scratching, rubbing, and biting of infested areas
	Haematopinus spp., *Linognathus* spp., and *Solenopotes* spp.	Sucking louse, cattle tail louse, long-nosed cattle louse, and little blue cattle louse	Cattle, sheep, goats, horses, and donkeys	Annoyance and blood loss. They can interfering with normal animal behavior, decreasing weight gain and milk production. Large numbers cause severe dermatitis and secondary infections. Animals may die, and pregnant cows may abort
	Bovicola spp.	Goat biting louse and angora goat biting louse	Sheep and goats	Annoyance and blood loss. They can interfere with normal animal behavior, decreasing weight gain and milk production. Large numbers cause severe dermatitis and secondary infections
Mites	*Sarcoptes* spp., *Psoroptes* spp., *Psorobia* spp., *Demodex* spp., and *Dermanyssus* spp.,	Scarbies mite, sheep itch mite, cattle follicle mites, goat follocle mite, chicken mite, chorioptic scab mite, and psoroptic ear mite	Cattle, sheep, goat, and poultry	Annoyance, skin/hide/wool damage, anemia, mal nutrition and death. They can interfere with normal animal behavior. Large numbers cause severe dermatitis and secondary infections and also decrease production

'Parasitism' in general refers to flies laying eggs in open wounds or where larvae invade unbroken skin or enter the body through the nose or ears. They could be divided into two categories: myiasis and pseudomyiasis. Myiasis is caused by flies that need a host for larval development or by flies' larvae that can develop in a host if open wounds or sores are present. Pseudomyiasis is referred to as the accidental deposit of eggs on oral or genitourinary openings caused by flies that have no preference or need to develop in a host. The impact of myiasis could be devastating. In 1989, more than 2.7 million animals distributed in 25 000 km^2 between the Mediterranean Sea and the Sahara Desert were infested in a single outbreak episode.

Indirect Consequence of Ectoparasites: Vector Transmission of Zoonotic Diseases

Among the wide variety of ectoparasites that could affect livestock, flies, and ticks are by far recognized as the major pests due to their competence as vector of several zoonotic diseases whose etiological agents may be protozoal, bacterial, or viral (Table 3). Unfortunately, from the increasing number of pathogenic vectorborne agents that can affect livestock throughout the world, relatively few are recognized as being of economic significance.

The following is a brief summary of the major vectorborne diseases in livestock worldwide.

Heartwater (Cowdriosis)

Heartwater is a septicemic, infectious tick-transmitted disease of cattle, sheep, goats, and other ruminants caused by *Ehrlichia ruminanti*um (Health, 2012). All domestic and wild subclinical-infected ruminants, including cattle, buffalo (*Syncerus caffer*), black wildebeest or white-tailed gnu (*Connochaetes gnou*), oryx (*Taurotragus oryx oryx*), giraffe (*Giraffe camelopardalis*), sable antelope (*Hippotragus niger*), Rusa deer (*Rusa*

Table 3 Major parasites groups as vectors of diseases: Vector species names, host, diseases, etiological agent, and occurrence. Information about the potential zoonotic transmission to humans is indicated

Vector	*Species*	*Host*	*Diseases*	*Etiological agent*	*Occurrence*	*Human*
Soft ticks	*Otobius* spp.	Cattle, sheep, goats, and rabbits	Q-fever	Coxiella burnetii	Worldwide	Yes
	Otobius spp.	Horses, cattle, sheep, goats, and rabbits	Tularemia	Francisella tularensis	Worldwide	Yes
	Ornithodoros porcinus	Domestic pig (*Sus domestica*), Warthog (*Phacochoerus aethiopicus*), wild boar (*Sus scrofa*), bush pig (*Potamochoerus* sp.), forest pig (*Hylochoerus meinertzhagen*)	African Swine fever	African Swine fever virus (*Asfarvirus* sp.)	Worldwide	
Hard ticks	*Rhipicephalus* spp., and *Ixodes* spp.	Cattle, water buffalo (*Bubalus bubalis*), African bufalo (*Syncerus caffer*), deer (*odocoeleus virginianus*), and reideer (*Rangifer tarandus*)	Bovine babesiosis (redwater)	*Babesia bovis*, *B. bigemina*, *B. divergens*	Worldwide	
	Dermacentor spp., *Hyalomma* spp., and *Rhipicephalus* spp.	Horses, mules, donkeys, and zebras	Equine babesiosis (piroplasmosis)	*Theileria equi* and *Babesia caballi*	Worldwide	
	Amblyomma spp.	*Bovidae* and *Cervidae* spp.: cattle, sheep, goats, deer, camelids, antelopes, giraffe, and wild ruminants	Heartwater	*Ehrlichia ruminantium*	Worldwide	
	Rhipicephalus spp., and *Hyalomma* spp.	Bovidae and Cervidae species: cattle, sheep, goats, deer, camelids, antelopes, giraffe, and wild ruminants	Theileriosis, East Coast Fever, Mediterranean theileriosis	*Theileria parva*, *Theileria annulate*	Worldwide, Africa, Mediterranean basin to China	
	Rhipicephalus spp., *A. variegatum*, and *Haemaphysalis* spp.	Sheep, goats	Nairobi sheep disease, Crimean Congo hemorrhagic fever	Nairobi sheep disease virus (NSD), Ganjam virus, Hazara virus	Africa and India	Yes
	Boophilus spp., *Dermacentor* spp., *Rhipicephalus* spp., *Ixodes* spp., *Hyalomma* spp., and *Ornithodoros* spp.	Cattle, sheep, deer, and goats	Bovine *Anaplasmosis* (gall sickness)	*Anaplasma marginale*, *A. centrale*, *A. ovis*, *A. bovis*, *A. caudatum*, *A phagocytophilum*	Tropical and subtropical regions	Yes
Mosquitoes, biting midges	*Aedes* spp., *Anopheles* spp., *Culex* spp., *Deinocerites* spp., *Mansonia* spp., *Psorophora* spp., *Coquiletidia* spp., *Ochlerotatus* spp., and *Simulium* spp.	Horses, donkeys, and zebras	Easter Equine Encephalitis (EEE), Venzuelan Equine encephalitis (VEE), Western Equine Encephalitis (WEE), West Nile Virus (WNV), Japanese Ecephalitis (JE)	Arbovirus (VEE, EEE, WEE, JE), Flavivirus (WNV)	North, Central and South America and the Caribbean (VEE and EEE) or USA (WEE), worldwide (WNV), and Japan (JE)	Yes

(*Continued*)

Table 3 Continued

Vector	*Species*	*Host*	*Diseases*	*Etiological agent*	*Occurrence*	*Human*
	Culicoides spp.	Cattle, sheep, goats, deer, camelids, antelopes, equines, and wild ruminants	Bluetongue, bovine ephemeral fever (Three Day Sickness), african horse sickness	*Orbivirus* spp., Ephemerovirus virus, Schmallenberg virus	Worldwide, Europe	
	Culex spp.	Sheep and goats	Nairobi sheep disease, Crimean Congo hemorrhagic fever	Nairobi sheep disease virus (NSD), Ganjam virus, Hazara virus	Africa and India	Yes
	Aedes spp., *Culex pipiens*, *Anopheles* spp.	Bovidae and *Cervidae* spp.: cattle, sheep, goats, deer, camelids, antelopes, wild ruminants	Rift Valley Fever	*Phlebovirus* spp.	Africa	Yes
	Aedes spp., and *Culex* spp.	cattle, sheep, goats, camelids, giraffe, antelope	Lumpy skin disease, sheep pox, goat pox	*Capripoxvirus* spp.	Africa, Middle east	
	Aedes spp.	cattle, sheep, goats, deer, camelids, horses, donkeys, swine	Vesicular stomatitis	*Vesiculovirus* spp.	Americas, Europe, and Africa	Yes
Biting flies	*Tabanus* spp., *Musca* spp., *Lyperosia* spp., and *Atylotus* spp.	Bovidae and Cervidae spp.: cattle, sheep, goats, deer, camelids, antelopes, wild ruminants	*Trypanosomiasis* (surra, nagana, Peste-boba, Tahaga)	*Trypanosoma evansi*, T. equinum, T. brucei, T. *vivax*, T. *congolense*	Worldwide	Yes
	Melophagus ovinus	Sheep	Bluetongue	*Orbivirus* spp., Ephemerovirus virus		
	Stomoxys calcitrans and *Biomyia mirificens*	Cattle, sheep, goats, camelids, giraffe, antelope	Lumpy skin disease, sheep pox, and goat pox	*Capripoxvirus* spp.	Africa, Middle east	
	Phlebotomus spp., and *Lutzomyia* spp.	Cattle, sheep, goats, deer, camelids, horses, donkeys, and swine	Vesicular stomatitis	*Vesiculovirus* spp.	Americas, Europe, and Africa	Yes

unicolor), white-tailed deer (*Odocoileus virginianus*), sitatunga (*Tragelaphus spekii*), steenbok (*Raphicerus campestris*), and lechwe (*Kobus leche kafuensis*), can serve as reservoir of the parasite.

Heartwater is transmitted by ticks of the genus *Amblyomma*. There are 13 species that can transmit the disease: *Amblyomma variegatum*, the tropical bont tick, is the most important vector due to its worldwide distribution. Other species are *Amblyomma hebraeum*, *Amblyomma gemma*, *Amblyomma lepidum*, *Amblyomma astrion*, *Amblyomma pomposum*, *Amblyomma cohaerans*, *Amblyomma marmoreum*, *Amblyomma sparsum*, *Amblyomma tholloni* (mainly distributed in southern, eastern and western African countries) and *Amblyomma maculatum* (the Gulf Coast tick), *Amblyomma cajennense* (the Cayenne tick), and *Amblyomma dissimile* (North America and the Caribbean).

The clinical pathologies associated with heartwater involve fever, anorexia, dyspnea, diarrhea, accumulation of reddish fluid in the pericardium (hydropericardium and hydrotorax), mediastinal and pulmonary edema, and submucosal and subserosal hemorrhages. In addition, tremors of superficial muscles and aggressive or anxious behavior may be present (OIE, World Organization for Animal Health, 2012; Health, 2012).

- No commercial vaccines are available at present. Attenuated bacterial strains used as vaccines (such as Gardel, Senegal, or Welgevonden strains) confer protection against homologous lethal challenges, but they induce limited or nonprotection against heterologous strain challenges. Inactivated vaccines using the Gardel or Mbizi strain or recombinant DNA vaccines do not prevent infection but rather confer some protection and reduction of death on animals exposed to a wide variety of live strains.
- As for many tick-transmitted infectious diseases, the most effective prophylaxis is the eradication or control (repellents and acaricides) of the tick vector.

African Swine Fever

African swine fever (ASF) is an enzootic tick-transmitted disease in domestic pigs (*Sus domestica*), European wild boar, and American wild pigs. The disease is caused by the ASF virus (ASFV), a DNA virus in the genus *Asfivirus* (Asfarviridae family) (Health, 2012). The natural reservoir of the virus are wild hogs, warthogs (*Phacochoerus aethiopicus*), bush pigs (*Potamochoerus* sp.), or the giant forest hogs (*Hylochoerus meinertzhageni*). Nevertheless, infected survivors, such as domestic swine, are virus carriers for life. The disease is transmitted by ticks of the genus *Ornithodoros*, but it can also be transmitted directly by contact between sick and healthy animals, by fomites (infected premises, vehicles, implements, and clothes), or by feeding on garbage, blood, tissues, secretions, or excretions of infected sick and dead animals (ASFV can remain infectious for 6 months in uncooked pork products).

The ASFV is endemic to the sub-Saharan Africa, including Madagascar. In Europe, it has been eradicated from Spain and Portugal, but it is present in Italy (Sardinia), Georgia, Azerbaijan, Armenia, and Russia. The ASFV was also reported in the Caribbean (Haiti and the Dominican Republic) and South America (Brazil), even though it was successfully eradicated.

The pathologies associated with the disease depend on the form (virulence) of the virus.

'Acute form' (highly virulent virus): fever, anorexia, diarrhea, vomiting, leucopoenia, thrombocytopenia, and abortion are common (OIE, World Organization for Animal Health, 2012). Reddening of the skin, especially in the tips of the ears, chest, abdomen, tail, and distal extremities may occur. Mortality rate in domestic swine may reach 100%. 'Subacute form and Chronic form' (moderately virulent virus): fever, light anorexia with weight loss, and abortion are common. Pericarditis, swellings over joints, and chronic skin lesions (ulcer and necrosis) have also been reported. The mortality rate in domestic swine is low and may vary between 30 and 70% (Health, 2012).

- As there is no vaccine or treatment for the disease, rapid slaughtering of all infected animals and proper disposal of cadavers and litter, as well as thorough cleaning, disinfection, and sterilization of garbage, are essential. Strict import or animal movement policy for animals and animal products from endemic or infected areas should be enforced.

Anaplasmosis

Anaplasmosis in ruminants (also known as bovine anaplasmosis and Gall sickness) is an infectious hemotropic disease of ruminants caused by several species of bacteria of the genus *Anaplasma*: *Anaplasma marginale*, *Anaplasma centrale*, *Anaplasma ovis*, *Anaplasma bovis*, *Anaplasma caudatum*, and *Anaplasma phagocytophilum* (Health, 2012). Cattle, sheep, or goats that have recovered from the clinical disease or other species of ruminants, such as water buffalo (*Bubalus bubalis*), white-tailed deer, mule deer (*Odocoileus hemionus hemionus*), black-tailed deer (*Odocoileus hemionus columbianus*), pronghorn (*Antilocapra americana americana*), Rocky Mountain Elk (*Cervus elaphus nelsoni*), bighorn sheep (*Ovis canadensis canadensis*), black wildebeest (*Connochaetes gnu*), blesbuck (*Damaliscus albifrons*), and duiker (*Sylvicapra grimmi grimmi*), can serve as reservoir. These pathogens are transmitted by several hard tick species of the genera *Boophilus* spp., *Dermacentor* spp., *Rhipicephalus* spp., *Ixodes* spp., *Hyalomma* spp., and *Ornithodoros* spp. In addition, athropods such as horse flies (*Tabanus* spp.) and mosquitoes (*Psorophora* spp.) (Blouin *et al.*, 2000; Kocan *et al.*, 2000, 2001, 2002, 2003, 2004a,b; de la Fuente *et al.*, 2002; Kocan and de la Fuente, 2003; De La Fuente *et al.*, 2004; de la Fuente *et al.*, 2005) and fomites (such as needles and surgical instruments that were in direct contact with blood-infected materials) could also be responsible for the transmission. Anaplasmosis is present in most tropical, subtropical, and in some temperate areas, which account for its worldwide distribution.

Anaplasmosis in characterized in the acute form by fever, anemia, weakness, anorexia, constipation, yellowing of the mucous membranes, dehydration, dyspnea, reduced or poor performance and milk production, and weight loss. Mortality could be as high as 70% (OIE, World Organization for Animal Health, 2012; Health, 2012).

- Several anaplasmosis immunization methods, using killed vaccine, attenuated live vaccine, or live *A. centrale* vaccine, have been used to protect cattle against anaplasmosis in countries where the disease is endemic with varying results (McHardy and Simpson, 1973; McHardy, 1974; McHardy *et al.*, 1980; Kocan *et al.*, 2001).
- Treatment of anaplasmosis depends on early diagnosis and prompt administration of an appropriate drug.
- As for many tick-transmitted infectious diseases, the most effective prophylaxis is the eradication or control (repellents and acaricides) of the tick vector.

Bluetongue

Bluetongue is a viral disease in sheep and cattle caused by several species of the genus *Orbivirus* (Health, 2012). There are 24 recognized serotypes of the bluetongue virus (BTV). The virus affects a wide range of ruminants, such as sheep, goats, cattle, buffaloes, white-tailed deer, pronghorn (*Antilocapra americana*), bighorn sheep (*Ovis canadensis*), African antelope, and other Artiodactyla species such as camels. Ruminants seem not to be the natural reservoir for the virus, because it does not establish persistent infections. The survival of the agent in the environment may be associated with insect or potentially with an unknown reservoir. The virus is transmitted among sheep and cattle by biting midges of the genus *Culicoides* and perhaps the wingless biting fly *Melophagus ovinus* (among sheep). Transmission occurs when midges feed on viremic animals and then on healthy individuals. Bluetongue is not a contagious disease; however, the virus can be spread mechanically on surgical equipment and needles. The distribution and prevalence of the disease is mostly associated with environmental factors (i.e., high rainfall, temperature, and humidity) and has a seasonal occurrence. The BTV has been found in many parts of the world, including Africa, Europe, the Middle East, Australia, the South Pacific, North and South America, and parts of Asia (Holbrook *et al.*, 1985; Osburn *et al.*, 1985; Parsonson *et al.*, 1985; OIE, World Organization for Animal Health, 2012).

The pathological signs and the severity of the infection varies widely, from asymptomatic to fatal, depending on factors related to agent, host, and environment. Some common lesions associated with the disease may include fever, congestion, edema, hemorrhages, and ulcerations of digestive and respiratory mucosae. Mucopurulent nasal discharges, excessive salivation, depression, dyspnea, and hyperemic of the muzzle, tongue, lips, face, eyelids, and ears are also common in susceptible animals. The tongue may become edematous and cyanotic protruding from the mouth. This symptomatology is what the disease is named after. In addition, hypertrophy of lymph nodes and splenomegaly have also been commonly reported. Morbidity in sheep can reach 100% with mortality between 30% and 70% in more susceptible breeds. In wild ruminants, especially white-tailed deer and pronghorn antelope, morbidity rate could reach 100%, with a mortality rate that can reach 90% (Health, 2012). It is estimated that the annual losses due to morbidity and mortality of animals, trade embargoes, and vaccination costs worldwide may be as high as US$3 billion (Anderson *et al.*, 1985; Holbrook *et al.*, 1985; Osburn *et al.*, 1985; Parsonson *et al.*, 1985; Osburn, 1994; Ward *et al.*, 1994; Osburn *et al.*, 1996; MacLachlan and Osburn, 2006). The estimated cost in the US cattle and sheep industry due to the loss of trade and the cost associated with diagnostic testing reaches US$125 million annually.

- Live attenuated and inactivated virus vaccines are available; however, they showed to be serotype specific. Nevertheless, attenuated or live vaccines should be used cautiously because the viruses in attenuated vaccines can be transmitted to unvaccinated animals and could reassort with field strains, resulting in new viral strains. In addition, vaccines can cause fetal malformations in pregnant ewes.
- As for most arboviral infections, the most effective control is to limit the spread or the occurrence of the disease by quarantine or limit the movement (housing) of animals; preventive vector control with insecticides such as synthetic pyrethroids or organophosphates is recommended.
- No treatment is available for infected animals.

Bovine Babesiosis

Babesiosis, or tick fever, is a febrile tick-transmitted disease of domestic and wild animals caused by several species of the genus *Babesia* (*Babesia bovis*, *Babesia bigemina*, *Babesia divergens*, *Babesia major*, *Babesia ovata*, *Babesia occultans*, and *Babesia jakimovi*), a protozoan parasite distributed worldwide (Barnett, 1974; Health, 2012). The natural reservoirs of the protozoan are subclinical infected ruminants, such as cattle, buffalo (*Bufalus bubalis* and *Syncerus caffer*), reindeer (*Rangifer tarandus*), and white-tailed deer. The protozoan does not survive outside of its hosts and is transmitted mainly by two genera of hard tick: *Rhipicephalus* spp. (*Rhipicephalus microplus*, *Rhipicephalus annulatus*, *Rhipicephalus decoloratus*, *Rhipicephalus geigyi*, and *Rhipicephalus evertsi*), which are vectors of *B. bovis* and *B. bigemina*; and *Ixodes ricinus*, which is vector of *B. divergens*.

Bovine babesiosis is found in areas where its arthropod vector is distributed, especially tropical and subtropical regions, including Africa, Asia, Australia, the Caribbean, and Central and South America (Montenegro-James, 1992; OIE, World Organization for Animal Health, 2012).

The pathologies associated with the disease depend on the parasite species and the age and immune status of the host. In general terms, clinical sings involve fever, anorexia, hemolytic anemia, hemoglobinuria, hepatosplenomegaly (enlarged spleen and liver), and production of dark red- or brown-colored urine. Ataxia, incoordination, and signs of general circulatory shock are common in *B. Bovis*-infected animals, where parasitemia generally does not exceed 1%. Hemoglobinuria and anemia are typical clinical signs of *B. Bigemina*- and *B. divergens*-infected animals, with reports of parasitemia levels of up to 30% (Health, 2012).

- Although vaccination is available through live vaccine (*B. bovis* and *B. bigemina*), the most effective prophylaxis is the eradication or control (repellents and acaricides) of the tick vector.

Theileriosis (East Coast Fever) and Tropical Theileriosis

East Coast fever and tropical theileriosis are tick-transmitted diseases caused by the protozoan parasites of the genus *Theileria* (OIE, World Organization for Animal Health, 2012; Health, 2012). Several ruminant species, including cattle, African buffalo (*Syncerus caffer*), Indian water buffalo (*B. bubalis*), and waterbuck (*Kobus* spp.), can be infected and can serve as reservoir, even though ticks can remain infected on the pasture for up to 2 years depending on the climatic conditions. The hard ticks of the genus *Rhipicephalus* are main vector for *Theileria*. There are six identified *Theileria* spp. that infect cattle. *Theileria parva* and *T.* mutants, the most important etiological agents of the East Coast fever, can be transmitted by *R. appendiculatus*, *Rhipicephalus zambeziensis*, and *Rhipicephalus duttoni*. East Coast fever is enzootic in East Africa and has been reported in Tanzania, Kenya, Uganda, Mozambique, South Africa, Rhodesia, Zaire, Rwanda, Burundi, Malawi, the Sudan, and most likely Ethiopia, Zambia, and Southern Somalia. *Theileria annulata*, the etiological agent of the tropical theileriosis, is transmitted by ticks of the genus *Hyalomma* and has a broader geographical distribution, including the Mediterranean Basin, North Africa, southern republics of the former USSR, the Middle East, and Asia. Other pathogenic *Theileria* species, such as *Theileria lestoquardi* (*Theileria hirci*), infect small ruminants in the Mediterranean Basin (Southern Europe and North Africa) as well as Asia (Barnett and Brocklesby, 1971; Brocklesby and Barnett, 1972; Morzaria *et al.*, 1974).

The most common pathological signs are in general nonspecific and mimic many other diseases. Clinical signs include fever, anorexia, lacrimation, corneal opacity, nasal discharge, terminal dyspnea, diarrhea, emaciation, dehydration, reduced or poor performance, and weight loss. In susceptible animals mortality could reach 100% (Health, 2012).

'The East Coast fever' is characterized by a generalized lymphadenopathy due to lymphocyte infection. Hyperplastic, hemorrhagic, edematous, and necrotic lymph nodes have been observed in acute cases of the infection. In addition, interlobular emphysema and severe pulmonary edema have also been reported. Lymphoid cellular infiltrations appear in the liver and kidney and hemorrhages and ulceration may be seen throughout the gastrointestinal tract.

'The tropical theileriosis' is characterized by macrophage infection that causes the release of cytokines (TNFα), anemia, and the presence of macroschizonts in infected macrophage-type cells.

- Immunization using live attenuated species (*T. parva* and *T. annulata*) or recombinant DNA vaccines seems to be reliable and robust against homologous challenges (Cunningham *et al.*, 1989).
- Treatment against *T. parva* and *T. annulata* can be done using chemotherapeutic agents, such as buparvaquone. Nevertheless, treatments with these agents do not completely eradicate infections. In those cases, animals become carrier. Interestingly, animals treated for *T. annulata* (but not for *T. parva*) develop complete cross-protection against most *Theileria* strains.
- As for many tick-transmitted infectious diseases, the most effective prophylaxis is the eradication or control (repellents and acaricides) of the tick vector (Minjauw *et al.*, 1998).

Trypanosomiasis

Trypanosomiasis, also known as surra, nagana, Peste-boba, Tahaga, Kaodzera, Baleri, Gambian horse sickness, Cachexial fevers, Dourine, mal de las caderas, etc., is a disease in cattle, buffaloes, sheep, goats, deer, camelids, antelopes, lamas, donkeys, horses, mules, deer, llamas, pigs, and elephants caused by a several flagellated protozoan species of the genus *Trypanosoma*: *Trypanosoma evansi*, *Trypanosoma equinum*, *Trypanosoma brucei*, *Trypanosoma vivax*, and *Trypanosoma congolense* (FAO–WHO, 1969; Takken *et al.*, 1988; Dargie *et al.*, 1993; Cecchi *et al.*, 2009; Ilemobade, 2009; Health, 2012). It is transmitted from animal to animal mechanically by hematophagous flies, including *Tabanus* spp., *Musca* spp., *Lyperosia* spp., *Stomoxys*, and *Atylotus* genera. In addition, hemophagous bats in South and Central America can serve as hosts, reservoirs, and vectors of *T. evansi* by transmitting the protozoan mechanically from animal to animal with their saliva or through biting flies (*Tabanus* spp., *Musca* spp., *Lyperosia* spp., and *Atylotus* spp.). Species such as *T. congolense*, *T. vivax*, *T. brucei*, *Trypanosoma Uniforme*, and *Trypanosoma simiae* are known as tsetse-transmitted trypanosomiasis where more than 23 species of Tsetse fly (*Glossina* spp.) act as biological vector. The tsetse-transmitted trypanosomiasis is the most economically important livestock disease in Africa, especially in cattle, affecting more than 37 countries with an estimated annual overall loss of US$6 billion year^{-1} (FAO–WHO, 1969; Dargie *et al.*, 1993; Hendrickx *et al.*, 1999; Cecchi *et al.*, 2008; Cecchi *et al.*, 2009).

The disease in characterized by the presence of a nonregenerative anemia, intermittent fever, edema, lacrimation, and enlarged lymph nodes, liver, and spleen. Infected animals also show decreased fertility, loss of appetite, affected body condition and productivity, emaciation, and early death (OIE, World Organization for Animal Health, 2012; Health, 2012).

- There is no vaccine available for trypanosomiasis.
- Treatment against trypanosomiasis may include diminazene aceturate and quinapyramine methylsulfate. Other drugs such as isometamidium chloride and quinapyramine sulfate and chloride can be used as prophylactic during transhumance or high seasonal parasitic pressure.
- For many tick-transmitted infectious diseases, the most effective prophylaxis is the eradication or control (repellents and acaricides) of the tick vector.

Eastern Equine Encephalitis, Venzuelan Equine Encephalitis, Western Equine Encephalitis, Japanese Encephalitis, and West Nile

Eastern, Western, and Venezuelan equine encephalomyelitis and the West Nile are mosquito-borne infections caused by several viral species and viral subtypes of the genera Alphavirus

(McConnell, 1972; Bigler and McLean, 1973; Gibbs, 1976; de Bellard *et al.*, 1989; Tsai, 1991; MacKay *et al.*, 2000; Castillo-Olivares and Wood, 2004; Anishchenko *et al.*, 2006; Davis *et al.*, 2008; Gibney *et al.*, 2011; Health, 2012). A common factor for all of them is that viruses normally cycle in bird populations and are transmitted mainly by mosquitoes. The Eastern equine encephalitis virus (EEEV) may also be able to persist in a wide range of animals, including mammals, birds, reptiles, and amphibians. The Venezuelan equine encephalitis virus (VEEV) seems also to be maintained in the sylvatic rodents or marsupials population (OIE, World Organization for Animal Health, 2012).

Eastern Equine Encephalomyelitis Virus

There are two variants for the EEEV, the North America and the Caribbean variant (more pathogenic) and the South and Central America variant (less pathogenic). The enzootic cycle of the infection is maintained most predominantly by mosquitoes of the genera *Culiseta*, a mosquito that primarily feeds on birds. Bridge vectors for EEEV include several species of mosquitoes of the genera *Coquilletidia*, *Aedes*, *Ochlerotatus*, and *Culex*. Mammals, including horses, humans, cattle, and small rodents, are considered to be incidental (dead end) hosts.

The maintenance and transmission of the virus inside the bird population (flock) can also occur by means of other vectors, such as in chicken lice, chicken mites (*Dermanyssidae*), and assassin bugs, or by direct transmission through feather picking and cannibalism.

Western Equine Encephalomyelitis Viruses

The Western equine encephalomyelitis virus (WEEV) is closely related to some other alphaviruses, including Sindbis, Ft. Morgan Aura virus, and the Highlands J viruses. WEEV has been isolated from Argentina to Western USA and Canada. The enzootic cycle of the infection with WEEV in maintained most predominantly by mosquitoes of the genera *Culex* and *Aedes*, which primarily cycles the virus between passerine birds and a variety of mammals, such as black-tailed jackrabbits (*Lepus califomicus*) acting as potential incidental hosts, or reptiles, such as snakes, frogs, and tortoises, which may serve as reservoir.

Venezuelan Equine Encephalomyelitis Viruses

The Venezuelan equine encephalomyelitis complex contains at least six viral subtypes. The VEE complex viruses (VEEV) are divided into epizootic (or epidemic) and enzootic (or endemic) groups. The epizootic viruses, which could be transmitted by several mosquito genera including *Aedes*, *Anopheles*, *Culex*, *Mansonia*, *Psorophora*, and possibly *Ochlerotatus*, are amplified in equines (horses, donkeys, and zebras) that serve as primary source of the virus during an outbreak. The epizootic group has been isolated in South and Central America.

The enzootic (sylvatic) subtypes are generally found in limited geographic areas, where they usually occur in natural cycles between rodents and mosquitoes. The enzootic subtypes, transmitted mainly by species of the *Culex* genera, are not amplified in equines and they are considered less pathogenic. The viruses of these subtypes have been isolated in South, Central, and North America.

In addition to mosquitoes, other vectors such as Black flies and mites can also mechanically transmit the epizootic viruses, meanwhile ticks of the genera *Amblyomma* and *Hyalomma* can be infected by both enzootic and epizootic VEEV strains.

West Nile Encephalomyelitis Virus

Mosquitoes of the genera *Culex*, *Aedes*, and *Anopheles* are the main vectors for the transmission of the West Nile encephalitis virus (WNEV) from wild birds. Humans and other small mammals (such as dogs) may harbor WNEV after being bitten; however, they are inefficient transmitters because viral titers are relatively low, and WNE viremia is in general short lived. The WNEV is endemic in Eastern Europe, the Middle East, Africa, and Asia, but it has been spreading to North America as recently as in 1999.

Clinical presentation of the infection involves lymphopenia, leukopenia, and fever as a result of the viral replication in macrophages and neutrophils. As the viral replication occurs in other tissues, such as in ancreas, adrenal cortex, heart, liver, and vasculature walls, variable degree of lesions, ranging from no lesion to extensive necrosis with hemorrhages, could be observed. As the infection progresses toward the central nervous system, neurological signs, such as sensitivity to sound, anxiety, periods of excitement, and restlessness, occur. Drowsiness, drooping ears, circling, aimless wandering, head pressing, inability to swallow, abnormal gait, and paralysis and death may follow as brain lesions appears. Mortality rates among horses could range from 70% to 90% (Health, 2012).

- Attenuated and inactivated virus vaccines are available for a number of combinations of viruses (EEEV/VEEV, EEEV/WEEV/VEEV, EEEV/WEEV/VEEV/tetanus toxoid, and EEEV/WEEV/VEEV/WNEV/tetanus toxoid.
- There is no cure for any of these viral diseases, but supportive measures (treating symptoms) are present. They may include antiinflammatory treatment (corticosteroids), anticonvulsants, intravenous fluids, tracheal intubation, and antipyretics.
- As for most arboviral infections, the most effective control to limit the spread or the occurrence of the disease is quarantine or limit the movement (housing) of the primary amplifiers (equids), preventive vaccination of animals, or the use of repellents or fans to limit the presence of mosquitoes.

Final Remarks

Ectoparasites and vectorborne pathogens will continue to present significant threats to human and animal health worldwide. On a global basis and especially in poor or developing countries, where they are the major economical impediments to efficient parasite control and efficient livestock production, the economic toll caused by ectoparasites and vectorborne diseases is staggering. The outbreaks of endemic disease, the threats of exotic disease introduction, and fears of

potential changes in arthropod distribution associated with climate change and animals movement have been the main reasons for changes in the nature of animal husbandry and parasite control. The livestock industry loses millions of dollars annually due to just external parasites control and prevention alone. Unfortunately, providing affordable and accessible parasite control and animal healthcare to producers in developing countries or poor livestock keepers worldwide remains a challenge.

A better understanding of the current distribution, prevalence, and control of ectoparasites coupled with a better domestic and international capability to detect, identify, and report vectorborne diseases would contribute substantially to improved meat and milk production worldwide.

Published by Elsevier Inc.

Glossary

Antivirals/biotherapeutics Class of medication to treat or prevent viral infections.
Immunity (adaptive) The mechanism of defense against pathogens found in vertebrates that is acquired after exposure to pathogens creating immune memory. Adaptive immunity is triggered by vaccines and foreign pathogens.
Immunity (innate) The mechanism of defense against pathogens present in plant and animal cells that functions in a nonspecific manner. This type of immunity is induced very rapidly after exposure to pathogens and before the adaptive immune response.
Interferons Proteins made and released by mammalian cells in response to the presence of pathogens including viruses, bacteria, parasites, or tumor cells. Interferons allow for communication between cells triggering protective defenses against pathogens or tumors.
Outbreak Occurrence of disease greater than expected in a particular time and place.
Surveillance Refers to an epidemiological practice by which the appearance and spread of disease is monitored in order to control it as fast as possible and to establish patterns of progression.
Transcription The first step in gene expression in which a particular segment of DNA is copied into RNA by the enzyme RNA polymerase.
Translation The process by which ribosomes decode messenger RNA (mRNA) into proteins.
Vaccines Biological preparation that confers immunity to a particular disease. A vaccine typically contains a weakened or killed form of the pathogen, or portions of the pathogen such as its surface proteins or toxins.
Virulence factors Molecules expressed and secreted by pathogens responsible for causing disease. Virulence factors allow the pathogen to colonize the host, evade immunity, and sometimes persist for long times.

Introduction

Foot-and-mouth disease (FMD) is one of the most contagious diseases of animals (Grubman and Baxt, 2004). The causative agent, FMD virus (FMDV), is the type species of the genus *Aphthovirus* within the *Picornaviridae* family (Grubman and Baxt, 2004). The virus is antigenically variable and consists of seven serotypes, A, O, C, Asia-1, South African Territories 1–3 (SAT1-3), and numerous subtypes and strains within each serotype.

More than 70 species of domestic and wild cloven-hoofed animals including cattle, swine, sheep, and goats are affected by FMD (Bachrach, 1968). The disease generally causes fever, lameness, and vesicular lesions on the tongue, snout, feet, and teats of susceptible animals often resulting in sloughing off of the epithelium and rupture of vesicles releasing copious amounts of virus (**Figure 1**). Disease signs can vary among species. In particular, sheep do not show overt signs of FMD (Alexandersen *et al.*, 2002d) and as a result an unnoticed infection of this species can spread an outbreak as rapidly as wild fire as it occurred in the United Kingdom in 2001 (Mahy, 2004).

FMD does not result in high mortality, except when young animals are infected. However, the disease can have significant debilitating effects including weight loss, reduced milk production, loss of draft power and mobility, resulting in a decline in productivity for a period of time. Infection of young animals can cause myocarditis and death as it occurred in the 1997 FMD outbreak in Taiwan, which caused an approximately 100% fatality rate in suckling pigs (Yang *et al.*, 1999).

Historically, FMD was probably first recognized in 1546 when the Franciscan monk, Hieronymus Fracastorius, described an outbreak in cattle in Italy that caused clinical signs similar to FMD (Fracastorius, 1546). Subsequently, in 1897 Loeffler and Frosch (1897) demonstrated for the first time that a filterable agent caused an animal disease, i.e., FMD. In the nineteenth and early twentieth centuries large numbers of FMD outbreaks occurred in many countries in Europe leading to the establishment of several institutes to study this disease. A vast amount of information has been obtained concerning FMD in more than 100 years since the seminal discovery by Loeffler and Frosch. As a result researchers have developed protocols and reagents to detect and control the disease and they continue to design novel approaches to improve disease control (see Section Disease Control Measures). However, despite this progress FMD continues to ravage many parts of the developing world, as well as causing frequent outbreaks in previously FMD-free countries. Moreover, after the 11 September 2001 attacks on the United States there is concern that FMD can be used as a weapon for bioterrorism.

FMD is currently present in many areas of the world including Africa, Asia, the Middle East, and a few countries in South America, whereas North America, Central America, Western Europe, Australia, and New Zealand are FMD free (**Figure 2**). The presence of the disease has a significant effect on the international trade of susceptible animals and their products. In particular the widespread presence of FMD in developing countries in Asia, Africa, and the Middle East has a substantial effect on the economies of many of these countries because a large proportion of their population lives in rural areas and depends on livestock for food and income (Cheneau *et al.*, 2003). Furthermore, the ability to block the spread of FMD to disease-free countries has become more difficult

 doi:10.1016/B978-0-444-52512-3.00195-9

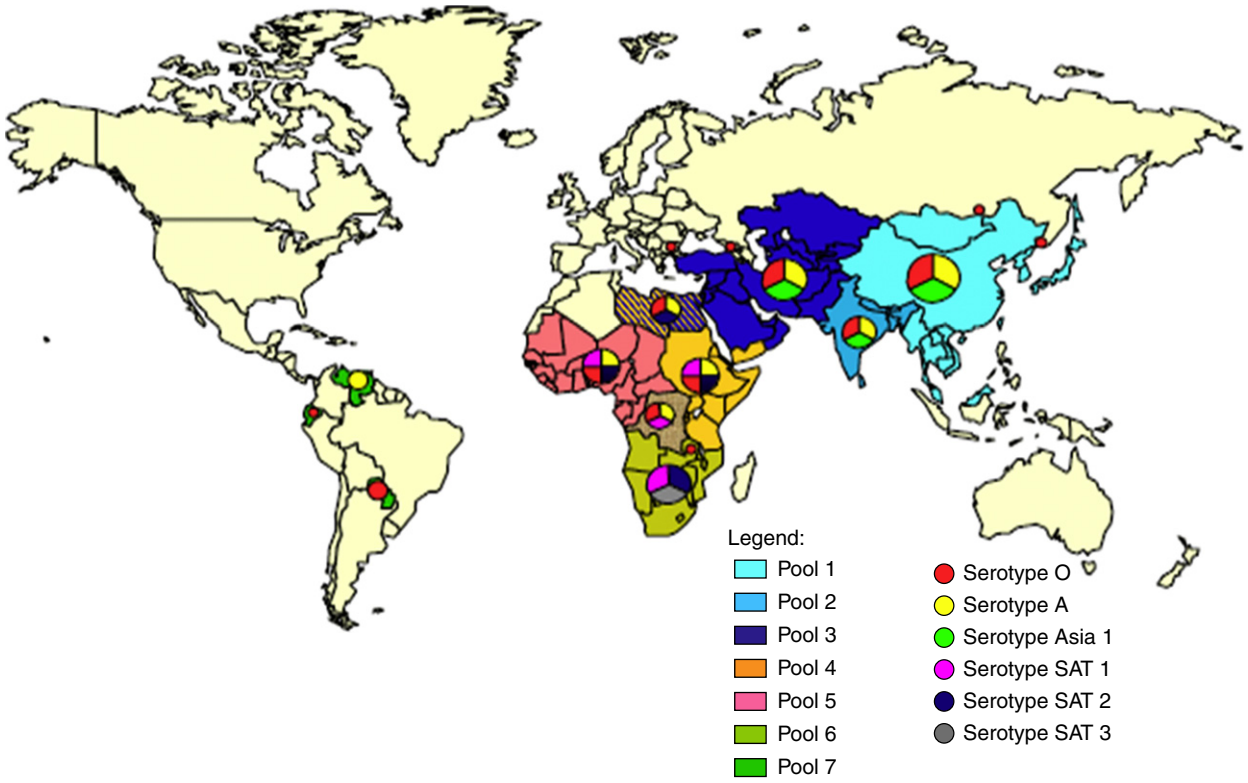

Figure 1 Countries affected by foot-and-mouth disease virus (FMDV). World map showing the different countries that reported an outbreak of FMDV between January 2010 and February 2013. Each color represents the different FMDV serotypes that affected the indicated region. Reproduced from Food and Agriculture Organization of the United Nations (FAO). European Commission for the control of FMD. Foot-and-Mouth Disease Situation. February 2013.

because of the globalization of trade and the rapid movement of goods and people worldwide. Thus, there are efforts led by the United Nations Food and Agriculture Organization (FAO) and the World Organization for Animal Health (OIE) to enhance veterinary service capabilities in developing countries so as to initiate disease surveillance programs and improve disease detection. In addition, there is also an urgent need to supply and deliver vaccines to these countries, which requires financial and human resources from developed countries and animal health organizations such as the FAO and the OIE.

In this article, the authors discuss many aspects of FMD including the molecular biology of the virus, disease pathogenesis, host immune response, disease outbreaks, and various approaches to disease control. The authors aim to make the reader aware of the severity of this disease and its impact on both animal and human health.

The Agent

Genome Organization

FMDV contains a positive-sense single-stranded ribonucleic acid (RNA) genome of approximately 8500 nucleotides (nt) covalently linked at the 5′ end to a virus-encoded protein (3B, also known as VPg) and packed into a nonenveloped icosahedral capsid. Figure 3 shows a schematic diagram of the FMDV genome displaying the predominant protein products that have been identified (Mason *et al.*, 2003). The FMDV genome displays a long open reading frame (ORF) flanked by highly conserved and structured untranslated regions (5′ and 3′ UTRs). The 5′ UTR of approximately 1300 bases contains five specific regions including the S fragment, poly(C) tract, pseudoknots (PKs), cre, and the internal ribosome entry site (IRES), which are required for efficient replication and translation (Grubman and Baxt, 2004; Mason *et al.*, 2003). Translation of the viral polyprotein begins after the IRES, at two alternative AUG codons and yields a large polyprotein of approximately 2300 amino acids that is co- and post-translationally processed by virus-encoded enzymatic activities into many precursor and mature products (Clarke and Sangar, 1988; Kirchweger *et al.*, 1994; Medina *et al.*, 1993; Ryan *et al.*, 1991; Vakharia *et al.*, 1987). Mature products include four structural (1A (VP4), 1B (VP2), 1C (VP3), and 1D (VP1)) and eight nonstructural (NS) proteins (L^{pro}, 2A, 2B, 2C, 3A, 3 copies of 3B (VPg), $3C^{pro}$, and $3D^{pol}$). The L protein is a cysteine protease (L^{pro}) that cleaves itself from the growing polypeptide chain and also cleaves many cellular factors playing a critical role in viral pathogenesis (Belsham *et al.*, 2000; Brown *et al.*, 1996; Falk *et al.*, 1990; Kirchweger *et al.*, 1994; Kleina and Grubman, 1992; Strebel and Beck, 1986). The P1 region encodes the four structural proteins, whereas P2 and P3 are precursors for the NS proteins that are mostly involved in viral RNA replication (Mason *et al.*, 2003). $3C^{pro}$ is the virus-encoded cysteine protease responsible for the majority of proteolytic cleavages in P1, P2, and P3 that result in

Figure 2 Common lesions of FMDV in cattle and swine. Vesicular lesions in the tongue and coronary bands of cattle (a and b) and pigs (c and d). (a) Ruptured vesicles on the tongue and along upper gum with sharp margins of lesions and red raw appearance of exposed dermis. (b) Foot of a steer with an unruptured vesicle in the heel-bulb. (c) Mouth of pig showing single, 1-day-old, unruptured vesicle at edge of tongue. (d) Swine feet with vesicles along the coronary bands of main and supernumerary digit with clear presence of sero-fibrinous in-filling.

mature viral products (Bablanian and Grubman, 1993; Vakharia *et al.*, 1987), and $3D^{pol}$ is the viral RNA-dependent RNA polymerase (RdRp).

Following the ORF there is a relatively short 3′ UTR of approximately 90 nt that folds into a specific stem-loop structure followed by a poly (A) tract of variable length. The 3′ UTR is also required for virus infectivity and replication (Pilipenko *et al.*, 1996; Saiz *et al.*, 2001; van Ooij *et al.*, 2006).

The three-dimensional structure of several FMDV serotypes has been determined by X-ray crystallography (Acharya *et al.*, 1989; Curry *et al.*, 1996; Fry *et al.*, 1999; Lea *et al.*, 1995; Lea *et al.*, 1994). The virus displays an icosahedral shape formed by 60 copies each of the four structural proteins. Although VP4 is buried on the inside of the particle, VP1 contains a prominent surface exposed loop, G–H loop, involved in the interaction between the virus and the integrin family of receptors in the host (O'Donnell *et al.*, 2005; Pierschbacher and Ruoslahti, 1984a,b). In comparison to other picornaviruses FMDV is quite unstable at a pH lower than 6.5 (Curry *et al.*, 1995; Ellard *et al.*, 1999), a feature that probably plays a role in targeting the virus to specific tissues and organs in susceptible hosts.

Virus Infectious Cycle

Several studies on the mechanism of FMDV entry have been reported (Grubman and Baxt (2004) and references therein). In tissue culture, FMDV can bind to four members of the αv subgroup of cellular integrins, $\alpha v\beta 1$, $\alpha v\beta 3$, $\alpha v\beta 6$, and $\alpha v\beta 8$, via the highly conserved RGD motif located on the G–H loop of VP1 (Monaghan *et al.*, 2005; O'Donnell *et al.*, 2009). However, the virus can utilize other membrane-bound molecules as receptors. Some FMDV field strains can be adapted to tissue culture by acquiring the ability to bind to cell surface heparan sulfate (HS) or other uncharacterized molecules (Baranowski *et al.*, 1998; Jackson *et al.*, 1996; Martinez *et al.*, 1997; Neff *et al.*, 1998; Sa-Carvalho *et al.*, 1997; Zhao *et al.*, 2003). *In-vivo* studies in cattle have shown that FMDV localizes only on epithelial cells of susceptible tissues that constitutively express

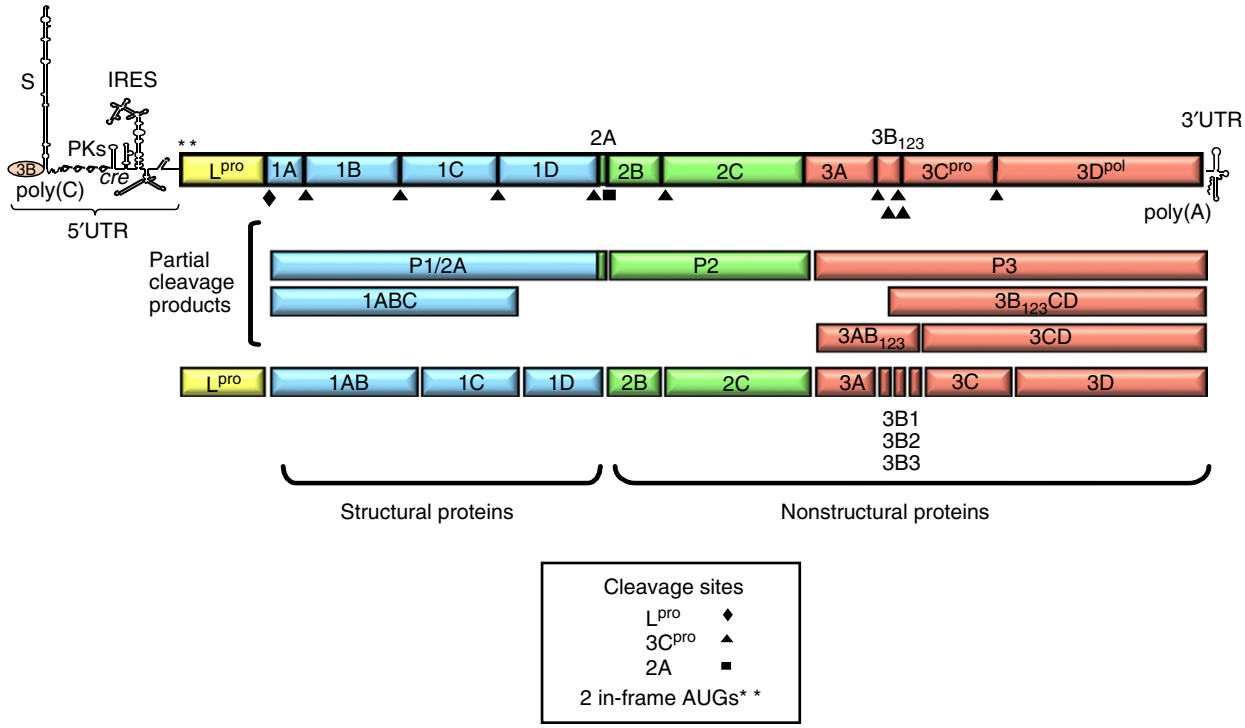

Figure 3 Genome organization of FMDV. RNA elements are shown at the 5′ and 3′ untranslated regions (UTR) and are represented as thin lines. The 5′ UTR consists of S fragment, poly (C) tract, pseudoknots (PKs), cis-acting replicative element (cre) and internal ribosome entry site (IRES). The ORF is depicted as outlined-open boxes. Filled triangles, squares, and diamonds indicate processing sites for $3C^{pro}$, 2A, and L^{pro}, respectively. Posttranslational proteolytic cleavages are shown as partial products as described in the text. Asterisks describe the two AUG initiation codons. The 3′ UTR consists of a short stretch of RNA and a poly (A) sequence. 3B (VPg) protein is shown as covalently linked to the 5′ end of the genomic RNA.

high levels of $\alpha v\beta 6$ integrin, suggesting that these molecules primarily mediate virus entry in the animal host (Brown *et al.*, 2006; Monaghan *et al.*, 2005; O'Donnell *et al.*, 2009).

With respect to the mechanism of virus entry, studies in cell culture expressing $\alpha v\beta 6$ integrins have demonstrated that FMDV serotypes A, O, and C use clathrin-dependent endocytosis (Berryman *et al.*, 2005; Martín-Acebes *et al.*, 2007; O'Donnell *et al.*, 2005). However, other mechanisms, such as caveola-mediated endocytosis, mediate internalization of FMDV through the HS receptor, indicating that the mechanism of entry depends on the specificity of receptor usage (O'Donnell *et al.*, 2008). Recently, it has been proposed that independently of the receptor utilized during cell entry, FMDV-induced autophagy facilitates infection (Berryman *et al.*, 2012).

On entry and uncoating of the viral RNA, the 5′ bound VPg protein is cleaved by a cellular enzymatic activity (Ambros and Baltimore, 1980; Ambros *et al.*, 1978; Gulevich *et al.*, 2002; Rozovics *et al.*, 2011) and translation begins at the IRES element (Belsham and Brangwyn, 1990; Kuhn *et al.*, 1990). IRES-dependent initiation of translation represents an alternative to the cap-dependent initiation mechanism that operates for most cellular messenger RNA (mRNAs) (Kozak, 1978). FMDV efficiently takes over the host translation apparatus by L^{pro}-dependent cleavage of the translation initiation factor eIF-4G (Devaney *et al.*, 1988; Kirchweger *et al.*, 1994). By 2–4 h postinfection cap-dependent cellular translation is basically shutoff and viral proteins are the major products detected in cell extracts.

As previously mentioned, the viral polyprotein is processed by three virus-encoded enzymatic activities including L^{pro}, 2A, and $3C^{pro}$ (Birtley *et al.*, 2005; Grubman and de los Santos, 2012a; Grubman *et al.*, 1995; Guarne *et al.*, 1998; Ryan *et al.*, 1991; Strebel and Beck, 1986). Following translation and polyprotein processing, the FMDV genome is replicated by the viral polymerase $3D^{pol}$ (Ferrer-Orta *et al.*, 2009; Ferrer-Orta *et al.*, 2006; Mason *et al.*, 2002; Nayak *et al.*, 2005; Pathak *et al.*, 2008; Paul *et al.*, 1998). RNA synthesis occurs within the cellular vesicles that derive from rearranged membranes of the endoplasmic reticulum and Golgi and contain most of the FMDV NS products and many associated host factors (Lawrence and Rieder, 2009; Martinez-Salas *et al.*, 2001; O'Donnell *et al.*, 2009; Pacheco *et al.*, 2009; Rozovics and Semler, 2010).

The final steps of the replication cycle involve encapsidation of the viral genomic RNA and maturation of the capsid. Only viral genomic RNA (plus strand) can be encapsidated and after encapsidation, the virion matures when the precursor VP0 is processed into VP2 and VP4 by an unknown mechanism (Curry *et al.*, 1995; Curry *et al.*, 1997; Knipe *et al.*, 1997; Nugent *et al.*, 1999).

Antigenic Variation

FMDV displays seven serotypes and multiple subtypes. New variants continuously arise due to the number of animal species that are susceptible to the virus, the different

environments the virus has adapted to, and the fact that viral replication relies on RdRps. RdRps are rapid and highly processive enzymes but display a fairly low fidelity resulting in high mutation rates (Ng *et al.*, 2008). This high error rate leads to significant differences of replicated genomes from the parental genome generating 'quasispecies' or 'cloud of mutants,' a phenomenon that has explained the evolution of replicating RNA molecules (Domingo *et al.*, 2002; Domingo *et al.*, 1980; Eigen, 1971). Most of the nucleotide changes in FMDV occur in the capsid-coding region and lead to antigenic variation. Some mutations may occur under immune pressure (Borrego *et al.*, 1993), whereas others become fixed even in the absence of immune pressure (Domingo *et al.*, 1993).

In addition to variation caused by mutation, FMDV has been shown to undergo RNA recombination in tissue culture and in field isolates (Jackson *et al.*, 2007; King *et al.*, 1985; Wilson *et al.*, 1988).

Antigenic variation is more common in the field and increases with time, probably as the result of repeated exposure and immune selective pressure of a highly diverse population of infected and vaccinated host species (Martinez *et al.*, 1992; Vosloo *et al.*, 1996).

Pathogenesis

FMDV infects a large variety of cloven-hoofed animals including many wild animals such as antelope, camel, deer, elephant, elk, giraffe, and llama. However, most pathogenesis studies have been focused on cattle, swine, sheep, and goats, given the serious economic consequences that an FMD outbreak may pose to the livestock industry. The ability of these viruses to infect such a variety of animal species challenges the analysis of the complex interactions between this agent and the host (Arzt *et al.*, 2011a,b).

Dissemination in the Host

In cattle and sheep the main route of infection is the respiratory tract. Swine are less susceptible to aerosolized virus and become infected by direct contact perhaps through abrasions on the vesicles present on the skin or mucous membranes of infected animals (Alexandersen *et al.*, 2003; Arzt *et al.*, 2011a, b; Grubman and Baxt, 2004). Virus is excreted into the milk (Burrows, 1968; Hyde *et al.*, 1975; Ray *et al.*, 1989) as well as in semen, urine, and feces (Donaldson, 1987; Kitching, 1992). The incubation period is dependent on the serotype, amount, and route of infection, but it is generally about 2 days or more.

A number of studies in cattle have shown that when animals are experimentally exposed to FMDV by aerosol, the virus primarily infects tissues of the upper respiratory tract (Alexandersen *et al.*, 2003; Brown *et al.*, 1992; Brown *et al.*, 1996; Sutmoller *et al.*, 1968). Arzt *et al.* (2010) have shown that tissues of the nasopharynx, dorsal soft palate, and to a lesser extent the lungs are the initial sites of FMDV replication. By 24 h postinfection the virus disseminates throughout the body and, although it reaches all organs, replication preferentially occurs at the sites where typical vesicular lesions appear including the coronary bands of the hooves, the mouth, the heart, and the adrenal glands (Arzt *et al.*, 2011a). Infected cattle also aerosolize large amounts of virus, which can infect naive cattle in addition to other species (Sorensen *et al.*, 2000).

In contrast to cattle, pigs are more refractory to aerogenous infection, but they are more susceptible to infection via the gastrointestinal route and generate greater quantities of aerosolized virus (Alexandersen *et al.*, 2002a; Alexandersen and Donaldson, 2002b; Alexandersen *et al.*, 2002d; Arzt *et al.*, 2011b). Pigs develop fever, viremia, and lesions on the feet and snout and young animals may develop fatal myocarditis.

Clinical disease in small ruminants is also characterized by lesions on the feet and mouth, fever, and viremia; however, disease is often subtle and can go undiagnosed (Kitching and Alexandersen, 2002). Although the specific sites of primary infection in sheep have not been well documented, it is likely that distinct phases within the upper and lower respiratory tract may occur as has been demonstrated in cattle (Arzt *et al.*, 2010; Arzt *et al.*, 2011b).

Carrier State

Similar to many other viruses, FMDV has evolved mechanisms to persist in the natural host. In general, the acute phase of infection is resolved within 14 days; however, some animals, mostly ruminants, experience a long asymptomatic chronic infection that can occur in both vaccinated and nonvaccinated animals (Alexandersen *et al.*, 2002c). These animals are referred to as carriers or persistently infected animals and by definition those are animals from whom infectious virus can be recovered from esophageal–pharyngeal fluids at 28 days or later after infection (Sutmoller *et al.*, 1968). However, it is not clear whether carrier animals transmit infection to naïve animals or what are the mechanism(s) that mediate the establishment and maintenance of such a state (Moonen and Schrijver, 2000; Salt, 1993; Sutmoller and Casas, 2002; Sutmoller *et al.*, 1968; Woodbury, 1995).

The carrier state has been documented for cattle, African buffalo, water buffalo, and to a lesser extent in sheep, goats, and other wild ruminants (Sutmoller and Casas, 2002). In cattle, FMDV can be detected in the epithelium of the pharynx and soft palate and in the light zones of the germinal centers in lymphatics of the pharyngeal region after the viremic period (Juleff *et al.*, 2008; Zhang and Kitching, 2001).

Studies in swine have shown that viral RNA could be detected in tissues at 28 days or longer postinfection, after viremia had been resolved (Mezencio *et al.*, 1999; Mohamed *et al.*, 2011; Zhang *et al.*, 2009); however, as no infectious virus could be recovered, by definition those animals were not considered carriers. More recently, Rodriguez-Calvo *et al.* (2011) have proposed a 'pseudopersistence state' in swine. Infectious FMDV C-S8c1 was isolated from different lymphoid tissues and the coronary band epithelia at 17 days postinfection; however, more studies are required in this species to evaluate if transmission to naïve animals is possible at later times.

Little is known about the mechanism that is involved in FMDV persistence, but involvement of the innate and adaptive responses have been suggested (Alexandersen *et al.*, 2002c; Baxt and Mason, 1995; Childerstone *et al.*, 1999; Guzylack-Piriou *et al.*, 2006; Mason *et al.*, 1993; Mason *et al.*, 1994);

Table 1 Involvement of nonstructural FMDV proteins in virulence

FMDV factors	*Affected process*	*Viral counter-mechanism*
L^{pro}	Translation and transcription	• eIF-4G-1 cleavage (de los Santos *et al.*, 2006, 2007; Devaney *et al.*, 1988; Kirchweger *et al.*, 1994) • Gemin5 cleavage (Pineiro *et al.*, 2012) • Decreased amounts of IFN-β (de los Santos *et al.*, 2007) • Degradation of NF-κB (de los Santos *et al.*, 2007) • Inhibition of RANTES (de los Santos *et al.*, 2006) • Deubiquitination of proteins involved in type I interferon pathway (TBK1, TRAF3, TRAF6)
2B + 2C and or 2BC	Membrane rearrangements, secretion and trafficking, and autophagy	• Inhibition of major histocompatibility complex class I surface expression and secretion of antiviral cytokines (Moffat *et al.*, 2005, 2007; Sanz-Parra *et al.*, 1998) • Modulation of cytophathogenicity (Arias *et al.*, 2010) • Induction of autophagy (O'Donnell *et al.*, 2001; Berryman *et al.*, 2012)
3A	Host tropism/viral RNA replication	• Unknown (Beard and Mason, 2000; Giraudo *et al.*, 1990; O'Donnell *et al.*, 2001; Sagedahl *et al.*, 1987)
3B	Viral RNA replication	• Primer for RNA synthesis. Sequence requirements in $3B_3$ (Arias *et al.*, 2010; Falk *et al.*, 1992; Pacheco *et al.*, 2003; Pacheco and Martinez-Salas, 2010)
$3C^{pro}$	Transcription and translation	• Histone H3 cleavage (Falk *et al.*, 1990) • eIF-4G and eIF-4A cleavage (Belsham *et al.*, 2000) • Sam68 clevage (Lawrence *et al.*, 2012) • NEMO cleavage (Wang *et al.*, 2012)

Robinson *et al.*, 2011). In any case, the role of carrier animals in the spread of virus in the field is controversial. As pharyngeal fluids contain virus and have high levels of neutralizing antibodies, it is unlikely that persistently infected animals could be the source of infectious virus (Bergmann *et al.*, 1996). The only direct evidence of transmission from African buffalo to cattle was reported during outbreaks in Zimbabwe in the late 1980s and early 1990s (Dawe *et al.*, 1994a) and in one study in which transmission from buffalo to cattle was experimentally obtained (Dawe *et al.*, 1994b). However, thus far, there is no conclusive evidence demonstrating that persistence plays a major role in FMDV transmission.

Virulence Factors

Virulence factors enable the virus to establish a niche for effective colonization and successfully evade the immune system. Several FMDV NS proteins and RNA regions of the genomic UTRs are known to disrupt or hijack cellular factors ultimately favoring virus replication and dissemination in the host (see **Table 1**).

Nonstructural Proteins

Virulence of L^{pro} was determined by developing a leaderless virus (Piccone *et al.*, 1995a) that was found to be highly attenuated in both cattle and swine (Brown *et al.*, 1996; Chinsangaram *et al.*, 1998; Mason *et al.*, 1997). Studies targeted to understand the attenuating effect of the leaderless virus demonstrated that L^{pro} is involved in blocking the innate immune response by interfering with translation and transcription of type I interferon (IFN-α/β) (Chinsangaram *et al.*, 2001; Chinsangaram *et al.*, 1999; de los Santos *et al.*, 2006; de los Santos *et al.*, 2007). Although blocking of host translation is primarily mediated by L^{pro}-specific cleavage of the translation initiation factor eIF-4G (Devaney *et al.*, 1988; Kirchweger *et al.*, 1994), inhibition of host transcription depends of the complex interplay of L^{pro} with several host factors.

A functional genomics approach using microarray technology and comparing the profiles of leaderless versus wild-type virus infected cells added supporting evidence. Thirty-nine out of 22 000 analyzed genes were differentially expressed in leaderless as compared with wild-type virus-infected cells and mostly included genes involved in the immune response (Zhu *et al.*, 2010). Apparently, this effect results from L^{pro}-dependent degradation or inhibition of activation of transcription factors that play key roles in immunity such as nuclear factor κB (NF-κB) and interferon regulatory factor 3/7 (IRF-3/7) (de los Santos *et al.*, 2007); Wang *et al.*, 2011a). Additionally, L^{pro} exhibits a deubiquitinase (DUB) function that affects many molecules involved in the regulation of type I IFN signaling pathways (Wang *et al.*, 2011b). Identification of L^{pro} cellular binding partners has been instrumental in the understanding of FMDV pathogenesis. Several cellular proteins such as eIF-4G, cyclin A and B, Gemin 5 and Daxx have been identified as direct interactors and targets of L^{pro} cleavage (Pacheco *et al.*, 2009; Pineiro *et al.*, 2012; Ziegler *et al.*, 1995). Thus, further exploration of these molecular interactions should provide additional insights into the L^{pro} function within highly complex cellular systems.

Similar to other viruses, FMDV can target and inhibit proteins that travel through the secretory pathway and are driven through the ER and Golgi organelles. Blockage of this pathway is common within the *Picornaviridae* family and is crucial for virus survival and evasion of the host immune system (Cornell *et al.*, 2006; Doedens and Kirkegaard, 1995; Netherton *et al.*, 2007). Overexpression of FMDV NS proteins 2B or 2BC induces membrane rearrangements thus hindering protein secretion (Moffat *et al.*, 2005, 2007; Pena *et al.*, 2008).

Interestingly, it has been reported that FMDV infection results in the downregulation of cell membrane attached MHC class I molecules, which play a key role in antigen presentation (Sanz-Parra *et al.*, 1998). Protein 2C has also been found in membranous aggregates along the periphery of FMDV-infected cells (Tesar *et al.*, 1989) and has been directly implicated in FMDV RNA synthesis and cytopathogenicity (Arias *et al.*, 2010; Caliguiri and Tamm, 1968).

The 3A protein plays a critical role in FMDV replication (Falk *et al.*, 1992; O'Donnell *et al.*, 2001). Attenuated strains containing partial deletions in 3A can be obtained by repeated passage of FMDV in chicken embryos (Giraudo *et al.*, 1990; Sagedahl *et al.*, 1987). Interestingly, a similar deletion was detected in the FMDV strain that caused a devastating outbreak in Taiwan in 1997 (O/TAW/97) mainly affecting swine but not cattle (Beard and Mason, 2000; Dunn and Donaldson, 1997). These results suggested that the NS 3A protein plays a critical role in FMDV pathogenesis and host restriction. The NS protein 3B is also critical for virus replication. FMDV contains three copies of 3B (VPg 1–3) and although viruses can be obtained with only one copy of VPg multiple copies are required for full infectivity (Arias *et al.*, 2010; Falk *et al.*, 1992; Pacheco and Martinez-Salas, 2010; Pacheco *et al.*, 2003). The role of FMDV $3C^{pro}$ in viral pathogenesis results from cleaving several host proteins. FMDV $3C^{pro}$ processes the host cell histone H3, leading to a block in cellular transcription (Falk *et al.*, 1990). In addition, $3C^{pro}$ targets the translation initiation factors eIF-4G and eIF-4A contributing to the L^{pro}-dependent shutoff of host cell translation (Belsham *et al.*, 2000), and the RNA-binding protein Sam68, which is required for efficient viral replication (Lawrence *et al.*, 2012). Interestingly, $3C^{pro}$ has been also shown involved in processing the NF-κB-essential modulator (NEMO) protein thus impairing IFN synthesis (Wang *et al.*, 2012). Cleavage of many host-specific proteins adds complexity to the multiple strategies FMDV has evolved to disarm the host immune response.

Untranslated Regions

The 5′ UTR of FMDV is more than 1300 bases in length (Forss *et al.*, 1984) and folds in complex secondary and tertiary structures that are involved in many aspects of viral replication and translation (see Section The Agent). Many host cellular proteins have been found to interact with the 5′ UTR and include PTBP, ITAF45, PCBP2, and nucleolin (Andreev *et al.*, 2007; Luz and Beck, 1990; Pacheco and Martinez-Salas, 2010; Pilipenko *et al.*, 2000). These proteins regulate IRES activity providing cell type specificity and determining virus spread, and some are cleaved during infection (Rodriguez-Pulido *et al.*, 2007). Other IRES-binding proteins, such as Gemin5, downregulate translation, but this effect is neutralized by L^{pro} (Pacheco *et al.*, 2009; Pineiro *et al.*, 2012). An additional host factor that binds specific sequences at the 5′ UTR is the RNA helicase A (RHA), which is required for viral replication (Lawrence and Rieder, 2009).

The RNA region located between the two AUG initiation codons (inter AUG) has been shown to be critical for the initiation of viral translation (Lopez de Quinto and Martinez-Salas, 1999; Piccone *et al.*, 1995a) although this effect can be cell type and serotype dependent (Belsham, 2013). Indeed, clinical studies have demonstrated that this region constitutes a virulence factor because disruption of the inter-AUG significantly reduced virulence of aerosolized FMDV A24 in cattle (Piccone *et al.*, 2010).

An important role of the 5′ UTR in virulence has also been demonstrated by testing the antiviral effect of antisense DNA oligomers targeting different regions of the IRES (Fajardo *et al.*, 2012; Vagnozzi *et al.*, 2007). However, these compounds have not been tested *in vivo* in the natural host.

In contrast to the 5′ UTR, the role of the 3′ UTR in virulence is limited. This region, which only spans 90 nucleotides, can fold into stable structures and presumably bridges the 3′ and 5′ UTRs during viral replication (Barton *et al.*, 2001; Herold and Andino, 2001; Pilipenko *et al.*, 1992). Although no molecular studies have confirmed this hypothesis, a role of the FMDV 3′ UTR in virulence has been proposed as viruses could not be recovered from genomes harboring a particular deletion of 74 bases in the 3′ UTR of serotype O1K (Saiz *et al.*, 2001). However, other studies have shown that viruses containing a 57 nucleotide insertion in the 3′ UTR of serotype A24 are fully virulent in cattle provided that conserved RNA structures are not affected by the insertion (Piccone *et al.*, 2009).

Autophagy and Virulence

Autophagy is a cell-regulated pathway that degrades and recycles long-lived proteins and cellular components (He and Klionsky, 2009). Unexpectedly, autophagy can be beneficial for viruses by providing specialized membranes for virus replication. It has been demonstrated by confocal microscopy that during FMDV infection, NS proteins 2B, 2C, and 3A and the structural protein VP1 colocalize with double-membrane (autophagosome) markers (O'Donnell *et al.*, 2011). Specifically, FMDV 2C has been associated with the autophagic markers Beclin-1 and vimentin (Gladue *et al.*, 2012; Gladue *et al.*, 2013). These findings suggest that autophagy plays a critical role in viral replication and could potentially promote persistent infection in relevant tissues where nonlytic release of the virus occurs (Alexandersen *et al.*, 2002c; Salt, 1993).

Host Immune Responses to Foot-and-Mouth Disease Virus

As a successful pathogen, FMDV has developed several mechanisms to evade the host innate and adaptive immune response. Understanding the host/pathogen interaction and the contributions of innate versus adaptive immune responses has become a central topic in FMDV research in order to be able to design new successful control strategies.

Innate Immunity

Foot-and-mouth disease virus is susceptible to interferon

IFNs are the first line of the host innate immune defense against viral infection in mammals (Ank *et al.*, 2006; Basler and Garcia-Sastre, 2002; Frese *et al.*, 2002). Pretreatment of cell cultures with all three types of IFN (I, II, and III) (Fensterl

and Sen, 2009) can dramatically inhibit replication of FMDV and it was shown that type I IFN can inhibit replication of all seven FMDV serotypes (Chinsangaram *et al.*, 2001; Chinsangaram *et al.*, 1999; Díaz-San Segundo *et al.*, 2011; Moraes *et al.*, 2007). FMDV counteracts the innate immune response, at least in part, by blocking the expression of IFN as a result of L^{pro} activity (see Section Virulence Factors). The action of the different types of IFN against FMDV is also very effective in the natural host (see Sections Disease Control Measures – Antivirals/Biotherapeutics).

Preliminary studies to understand the molecular mechanisms induced by IFN treatment that result in protection against FMDV challenge showed a correlation with specific IFN-stimulated gene (ISG) upregulation and tissue-specific infiltration and partial maturation of dendritic cells (DCs) in the skin and natural killer (NK) cells in draining lymph nodes (Diaz-San Segundo *et al.*, 2013b; Diaz-San Segundo *et al.*, 2010; Moraes *et al.*, 2007). Cell culture studies with IFN demonstrated that at least two ISGs, double-stranded-RNA-dependent protein kinase and 2′, 5′ oligoadenylate synthetase/RNase L, are involved in this process (Chinsangaram *et al.*, 2001; de los Santos *et al.*, 2006; Moraes *et al.*, 2007). Furthermore, the 10-kDa IFN-γ-inducible protein (IP-10) is also directly involved in the protection conferred by type I IFN as demonstrated using a mouse IP-10 knockout model treated with IFN-α before FMDV challenge (Diaz-San Segundo *et al.*, 2013a).

Foot-and-mouth disease virus interacts with cells of the innate immune system

During the course of infection, the virus interacts with different DC populations (Bautista *et al.*, 2005; Diaz-San Segundo *et al.*, 2009; Lannes *et al.*, 2012; Nfon *et al.*, 2008; Nfon *et al.*, 2010; Ostrowski *et al.*, 2005; Reid *et al.*, 2011; Robinson *et al.*, 2011), NK cells, and macrophages either by direct infection or as a consequence of DCs phagocytosing the virus in peripheral tissues for antigen presentation (Merad and Manz, 2009; Vivier *et al.*, 2011).

FMDV can infect conventional DCs (cDCs) *ex vivo*, although in most cases this interaction is abortive and no virions are produced (Diaz-San Segundo *et al.*, 2009; Ostrowski *et al.*, 2005). However, it has been demonstrated in cattle that the presence of specific anti-FMDV antibodies enhances infection through the interaction of virus–antibody complexes with FcγR receptors located on the surface of cDCs resulting in productive infection and cell death (Robinson *et al.*, 2011). In addition, FMDV can modulate adaptive immune responses as a result of its interaction with DCs. During acute infection, the virus stimulates DCs to produce interleukin (IL)-10, thus directing adaptive immunity toward the development of a stronger humoral response (Diaz-San Segundo *et al.*, 2009; Robinson *et al.*, 2011). Although it has been shown that interaction of FMDV with bovine cDCs *in vitro* results in productive infection, attempts to recover virus from DCs derived from FMDV-infected swine have been unsuccessful. Nevertheless, FMDV affects monocytes extracted from pigs during acute stages of FMDV blocking their ability to differentiate into mature cDCs (Diaz-San Segundo *et al.*, 2009) and to respond to stimulation with toll-like receptor (TLR) ligands (Nfon *et al.*, 2008).

Swine Langerhan cells (LCs) are also affected by FMDV (Bautista *et al.*, 2005; Nfon *et al.*, 2008). *Ex-vivo* studies demonstrated that FMDV is able to attach and become internalized in these cells; however, there is no evidence of viral RNA replication or production of viral proteins (Bautista *et al.*, 2005). Furthermore, LCs from FMDV-infected pigs showed a reduction in IFN-α production after *ex-vivo* stimulation, although their ability to present antigen is unaffected (Nfon *et al.*, 2008). Clearly, DC antigen presentation is preserved during FMDV infection resulting in a rapid and strong adaptive immune response and virus clearance.

Plasmacytoid DCs (pDCs) are poorly activated by FMDV *in vitro* (Lannes *et al.*, 2012), although when live virus is internalized as part of immune complexes bound to FcγRII surface receptors, the activation is more efficient for either porcine or bovine cells (Guzylack-Piriou *et al.*, 2006; Reid *et al.*, 2011). In any case, the level of IFN-α induction is highly serotype dependent and uptake of these complexes results in abortive virus replication. Furthermore, it has been demonstrated that the level of systemic type I IFN increases during FMDV infection in cattle and is mainly produced by pDCs (Reid *et al.*, 2011). Nfon *et al.* have found that during acute FMDV infection in swine, the pDC population is depleted in blood, although there is a peak of IFN in serum at the same time of the peak of viremia (Nfon *et al.*, 2010). However, *ex-vivo* production of IFN after the stimulation of pDCs with TLR ligands from infected animals is inhibited (Nfon *et al.*, 2008). These results suggest that the pDC response in animals infected with FMDV vary depending on the animal species and the specific FMDV serotype involved.

Macrophages are fundamental for rapid 'clean up' of viral pathogens at the sites of infection. Similar to DCs, FMDV also utilizes an antibody-dependent internalization process via the FcγRII receptor to enter macrophages (Baxt and Mason, 1995; McCullough *et al.*, 1988). Interestingly, it has been reported that, in the absence of productive infection of porcine macrophages, FMDV remains infectious for 10–24 h after internalization by macrophages (Ridgen *et al.*, 2002). Implications of these observations favor the role of macrophages as transporters and disseminators of viable virions to distant sites of the body where the virus can infect and replicate in other cells.

NK cells occupy a critical position during the initial host response against pathogens, particularly during viral infections (Vivier *et al.*, 2011). It has been demonstrated that during FMDV infection of swine there is a reduced capacity of NK cells to lyse target cells and secrete IFN-γ (Toka *et al.*, 2009). NK cell dysfunction during the viremic phase of acute FMDV infection suggests that the virus can effectively block NK function and evade the host's immune response allowing the virus to replicate and disseminate within the host. However, the mechanism involved in this blockage remains unclear.

Adaptive Immunity

Humoral responses

It is well established that the clearance of FMDV occurs through an early potent secretion of neutralizing antibodies starting from day 4 after viral infection. The early B-cell response to FMDV infection in cattle is characterized by the

presence of IgM in lymphoid organs of the upper respiratory tract and serum by 4 days postinfection followed by the detection of IgA and then IgG peaking 1–2 weeks later (Collen *et al.*, 1989; Juleff *et al.*, 2009; Pega *et al.*, 2013; Salt *et al.*, 1996). In infected swine, a similar response is detected (Pacheco and Martinez-Salas, 2010). Interestingly, several groups have demonstrated that the production of antibodies is T-cell independent (Borca *et al.*, 1986; Collen *et al.*, 1989; Juleff *et al.*, 2009; Pega *et al.*, 2013).

T-cell response

Swine develop severe but transient lymphopenia and lymphoid depletion in all the lymphoid organs during the acute phase of FMDV infection. All T-cell subsets, as well as B cells, are affected and depletion of lymphocytes correlates with the appearance of viremia (Bautista *et al.*, 2003; Diaz-San Segundo *et al.*, 2006). In addition, the function of T cells during this early stage of infection is significantly impaired. Thus, FMDV rapidly induces an immune-depressed state in infected swine that recovers by 4–7 days after infection when viremia is abating. These early events provide very favorable conditions for the virus to both spread systemically and shed into the environment. Although lymphopenia is a well-characterized event in swine, the mechanisms involved are not completely understood. It has been reported that infection of lymphocytes is a possible cause of lymphopenia in both swine and cattle (Diaz-San Segundo *et al.*, 2006; Joshi *et al.*, 2009). However, other groups have failed to detect productive infection of peripheral blood mononuclear cells during the course of FMD (Bautista *et al.*, 2003). Nfon *et al.* (2008) have proposed that lymphopenia in swine can be caused by an increase in the amount of systemic IFN during FMDV infection. However, this IFN production was not reproducible for all FMDV serotypes. Finally, it is possible that the diminished T-cell responses could be related to the elevated amounts of IL-10 produced by the cDCs during infection (Diaz-San Segundo *et al.*, 2009; Ostrowski *et al.*, 2005), as IL-10 has been reported to have a role in inducing immunosuppression *in vivo* (Brooks *et al.*, 2006). Similarly, lymphopenia and inhibition of T-cell response to mitogen has also been demonstrated in cattle (Joshi *et al.*, 2009; Perez-Martin *et al.*, 2012), although immunocompetency throughout the FMDV infection has been also reported (Windsor *et al.*, 2011). Apparently, strain- and species-specific immune responses may account for the differences in the observed responses.

Disease Outbreaks

In Disease-Free Countries

FMD was first described in Italy in 1546 (Fracastorius, 1546) and subsequently outbreaks were reported in France, Germany, and the UK in the from the seventeenth to the nineteenth centuries (Mahy, 2004). The earliest reports of FMD in South America, North America, Asia, and Africa were in the nineteenth century. In the United States, the first FMD outbreak was reported in 1870 and subsequently there were eight additional outbreaks with the last occurring in 1929. During this period, disease control consisted of inhibition of animal movement, stamping-out of infected and in-contact animals, and disinfection of affected premises.

In the early 1950, some countries in Western Europe experienced thousands of outbreaks, which were not controlled by existing strategies. As a result, vaccination with an inactivated whole-virus antigen was introduced and resulted in a dramatic decrease in the number of outbreaks. By 1992, The European Union had adopted a no-vaccination policy (Brown, 1992). However, from the late 1990s to the early twenty-first century a number of outbreaks occurred in developed countries that had been FMD free for many decades. These outbreaks were mainly the result of the spread of FMDV type O viruses. In 1997, an outbreak occurred in Taiwan, which had been FMD free for 68 years, spreading to almost the entire island in less than 3 weeks (Yang *et al.*, 1999). Eventually, slaughter and vaccination were required to control the disease and the outbreak resulted in the culling of more than 4 million pigs at a cost of approximately US$6 billion. Unfortunately, Taiwan has never regained its FMD-free status and continues routine FMD serological surveillance. As recently as May 2013, an outbreak of serotype O was reported.

In the next few years, FMDV type O outbreaks occurred in South Korea and Japan for the first time in 66 and 92 years, respectively. The South Korean outbreak was relatively large affecting approximately 500 000 animals, and was controlled by slaughter and vaccination (Joo *et al.*, 2002), whereas the outbreak in Japan was limited and controlled by slaughter (Sakamoto and Yoshida, 2002). In February 2001, an outbreak was discovered in the UK. By the time the outbreak was detected it had already spread to many counties and ultimately resulted in the culling of approximately 6.5 million animals with an estimated cost of US$12–14 billion (Scudamore and Harris, 2002). Subsequently, the virus spread to Northern Ireland and France, presumably as a result of the presence of infected sheep imported from the UK, but the disease only affected a few farms and was controlled by slaughter. In March 2001, the disease was confirmed in The Netherlands (Pluimers *et al.*, 2002). Approximately 200 000 animals were vaccinated and slaughtered. In contrast the UK controlled the disease only by inhibition of animal movement and slaughter of infected animals. As a result of the slaughter of large numbers of animals in these outbreaks, many of which were disease free, the public questioned the validity of this policy. In response to this concern the OIE in 2002 changed their recommended policy on vaccination and allowed a country to regain FMD-free status after vaccination without slaughter in 6 months rather than 12 months, whereas countries that slaughtered or vaccinated and then slaughter can regain FMD-free status in 3 months. Nevertheless, the new OIE policy increased the likelihood that countries would utilize alternative approaches other than culling to control FMD.

Uruguay had been declared FMD free without vaccination in 1996, but outbreaks occurred in 2000 and early 2001 (Sutmoller *et al.*, 2003). The first outbreak was limited and controlled by stamping-out. The second outbreak was quickly detected and initially animals on the affected farms were depopulated, but the disease spread and a 'ring-vaccination' program was soon implemented followed by national vaccination of all cattle. In contrast to the UK, only a small number of animals were destroyed, and Uruguay's beef exports

resumed within a year. The cost of the control program was approximately US$14 million.

In 2007, another FMD outbreak occurred in the UK close to the Pirbright facility, which houses both the Merial FMD vaccine production plant and the Institute of Animal Research which conducts basic and applied research (Cottam *et al.*, 2008). The outbreak strain, type O1 BFS 1860, was traced to ongoing work at both Pirbright laboratories, and was contained to just eight farms surrounding the Pirbright facility because of rapid identification of the disease. Even though the disease was limited it still resulted in an estimated loss of greater than £100 million.

In April, 2010 a large FMD outbreak caused by type O virus occurred in Japan (Nishiura and Omori, 2010). A number of FMD-susceptible species were infected and more than 276 000 animals were culled including seed bulls on a farm that supplied 90% of the sperm used for cattle production in the Miyazaki prefecture. Although veterinarians initially reported disease signs in buffalo at the end of March and disease in cattle on another farm it was not until 3 weeks later that FMDV was confirmed by laboratory analysis. Initially, culling and a ban on livestock movement were imposed to control the disease, but because the number of infected farms rapidly increased emergency vaccination of all FMD-susceptible farm animals around the infected premises was started. FMDV had reemerged in South Korea in 2010 and again in the winter of 2010–11 and was the result of serotypes A and O, respectively (Park *et al.*, 2012; Yoon *et al.*, 2012). The later outbreak was the largest ever recorded in South Korea and was closely related to the type O virus that caused the 2010 Japanese outbreak. The disease affected cattle, pigs, sheep, and goats. Initially, infected farms were depopulated, but subsequently emergency vaccination was used.

The outbreaks in Taiwan in 1997, the UK in 2001, and in Japan in 2010 again demonstrated that if there is a delay in recognizing FMD it is extremely difficult to adequately limit and control its spread, whereas the rapid identification of the disease in the 2007 outbreak in the UK clearly limited its spread.

In Enzootic Countries

FMD is currently enzootic in many Asian, African, and Middle-Eastern countries. Many of these countries do little to control the disease because of the lack of resources. In 2013 alone numerous outbreaks have occurred in China, Russia, Taiwan, Tanzania, Zimbabwe, Botswana, and other countries. Of particular concern is the spread of some serotypes to geographical areas in which these viruses have not previously been reported and therefore the susceptible animal population has no immunity. For example, the movement of the SAT-2 virus from Southern Africa to Saudi Arabia in 2000 was the first report of this serotype in Saudi Arabia. More recently in 2012, SAT-2 was reported in Egypt and caused a large outbreak in cattle.

Disease Control Measures

Surveillance

Control of FMD requires a concerted effort by the individual livestock owner, private veterinarians, and by the country's veterinary services. Since FMDV replicates and spreads extremely rapidly it is essential that infected animals are detected very quickly requiring both vigilance on the part of the livestock owner as well as knowledge of disease signs. Unfortunately, even in developed countries with presumably knowledgeable livestock owners and a trained veterinary service, FMD outbreaks may still go undetected until the disease has spread beyond the initial site of infection. This can partially be due to infection of sheep or goats that often do not show easily detectable disease signs, due to a delay in reporting the index case, or due to a lack of reporting because of illegal feeding of swine with improperly treated swill (Mahy, 2004). In the 2001, UK FMD outbreak the first infected animals were pigs on a farm in Northumberland that were not reported for approximately 3 weeks and in the mean time resulted in the subsequent infection of sheep on the neighboring farms that were moved to various parts of the country without showing apparent clinical sings (Scudamore and Harris, 2002).

Diagnostics

An essential component of a disease control strategy is the use of diagnostic assays to rapidly confirm or eliminate clinically suspect animals. For FMD this is especially important as there are a number of diseases including swine vesicular disease, vesicular stomatitis, and vesicular exanthema of swine, which cause vesicular lesions in swine and cattle that cannot be distinguished from FMD (Bachrach, 1968). After positive diagnosis of FMD, it is also necessary to identify the serotype and strain of the virus as this information is necessary to choose the appropriate antigen to use in vaccination-to-slaughter or vaccination-to-live campaigns. Sensitive diagnostic assays are also needed to distinguish infected animals from vaccinated animals and perform epidemiological surveillance to confirm the naïve status of animals in the field in order to allow for resumption of international trade.

Currently, the OIE suggests the use of a number of diagnostic techniques depending on the type of field samples obtained. The recommended tissue of choice is epithelium or vesicular fluid, but other samples including serum or esophageal–pharyngeal (OP) fluids can also be used. Virus isolation, virus neutralization, reverse-transcription polymerase chain reaction (RT-PCR), enzyme-linked immunosorbent assay (ELISA), or complement fixation assays can be used to identify FMDV. More recently, lateral flow devices are being developed to allow for rapid pen-side testing.

The need for rapid diagnosis is critical. Currently, FMD is confirmed by ELISA, which takes approximately 3–4 h. A negative result must be confirmed by virus isolation in tissue culture, which can take up to 4 days and is not compatible with a rapid response. Therefore, more recently RT-PCR and real-time RT-PCR assays have been developed. Results from the later assay can be obtained in 2 h (Callahan *et al.*, 2002). To differentiate infected animals from vaccinated animals a number of tests have been developed. These are all based on the premise that infected or convalescent animals have antibodies to the viral NS proteins as well as the viral structural proteins, whereas vaccinated animals should only have

antibodies to the viral structural proteins. Unfortunately, this later observation is not necessarily correct as the current inactivated vaccine may contain various amounts of NS proteins depending on the degree of purity of the vaccine preparation (Doel, 2003; Lubroth *et al.*, 1996). A currently validated ELISA uses *E. coli* or baculovirus produced NS protein 3ABC to differentiate infected animals from vaccinated animals. Another assay uses more than one NS protein to unambiguously identify infected animals. This assay, developed by scientists at the OIE Reference laboratory in Rio de Janeiro, is a Western blot of five viral NS proteins expressed in *E. coli* (Berger *et al.*, 1990; Bergmann *et al.*, 1993; Bergmann *et al.*, 2000).

Vaccines

The current FMD vaccine is an inactivated whole-virus preparation that is formulated with various adjuvants before use. As FMDV is an antigenically variable virus, different vaccines are required for each serotype and often different vaccines are necessary to protect against various strains or subtypes within a serotype. The vaccine is produced by infection of suspension cultures of BHK-21 cells with live virus and therefore production requires a high-containment facility. In-depth reviews by Doel (Doel, 2003) and Barteling (Barteling and Cassimi, 2004) discuss the history, production, and testing of inactivated FMD vaccines.

Various countries have established regional FMD vaccine banks that maintain vaccines against circulating viruses (Doel, 2003; Grubman and Baxt, 2004). The United States, Canada, and Mexico in 1982 established the North American FMD Vaccine Bank which is located at the Plum Island Animal Disease Center (PIADC) off the coast of Long Island, NY and is jointly administered. Initially, vaccines were stored as formulated antigen that only had approximately a 1-year shelf life. More recently, vaccine banks store concentrated antigen in the gaseous phase of liquid nitrogen (Doel, 2003) to increase antigen shelf life (Doel and Pullen, 1990). However, to be used in the field the concentrated antigen has to be shipped back to the manufacturer for formulation and returned to the country where the outbreak is occurring. To maintain concentrated FMD antigen that will be protective against circulating FMDV strains it is necessary to continually monitor virus in the field and determine if these strains are sufficiently related to available vaccine antigen. If not appropriate, new vaccine strains have to be produced.

Although inactivated FMD vaccines have been effective in eliminating FMDV from Western Europe and some countries in South America, there are a number of concerns with their use and as a result vaccination has often not been used as part of an FMD disease control approach. (1) As already mentioned production of inactivated FMD vaccines requires expensive high-containment facilities and effective virus inactivation. Unfortunately, the 2007 FMD outbreak in the UK was the result of escape of live virus from the Pirbright FMD facility. (2) Vaccine production requires passage of live virus in BHK-21 cells. There is evidence that passage of virus in cell culture can result in the selection of antigenic variants with altered receptor binding, antigenic structure, and virulence (Bolwell *et al.*, 1989). (3) Depending on the purity of the vaccine antigen produced by various manufacturers it can be difficult to serologically distinguish infected animals from vaccinated animals (Grubman and Baxt, 2004). To address this concern new animal vaccines require markers that allow for differentiation of infected animals from vaccinated animals (DIVA). (4) Vaccinated cattle can become long-term carriers following contact with FMDV-infected animals. (5) The United States cannot produce FMD vaccine as the current Federal law only allows work with FMDV to be conducted at the PIADC and this facility does not have a high-containment manufacturing plant. Thus, in the event of an FMD outbreak in the United States, Canada, or Mexico the correct concentrated antigen present in the bank would have to be shipped overseas to the manufacturer for formulation and bottling and shipped back for distribution. (6) The current vaccine can only induce protection in approximately 7 days. Thus, there is a window of susceptibility if vaccinated animals are exposed to live virus before the induction of an adaptive immune response.

Owing to these limitations, for the past 40 years researchers have attempted to develop new vaccines that can address some or all of these concerns (as reviewed in Doel, 2003; Fowler and Barnett, 2012; Grubman, 2003; Mason and Grubman, 2009; Parida, 2009; Rodriguez and Grubman, 2009). In this article, the authors mainly focus on the latest developments in the most advanced vaccine approaches. Importantly, all of the new vaccine approaches described includes DIVA markers.

New subunit vaccine candidates

The initial attempts to produce vaccines that addressed some of the limitations of the inactivated vaccine included inoculation of susceptible animals with viral structural protein VP1 or a fragment of VP1 (Bachrach *et al.*, 1975; Kleid *et al.*, 1981; Strohmaier *et al.*, 1982; see Grubman and Baxt, 2004 for references). This approach and its limitations have been extensively reviewed (Grubman, 2003; Taboga *et al.*, 1997). In another approach researchers have attempted to utilize empty virus particles as the immunogen. Empty viral capsids or virus-like particles contain all of the epitopes present on intact virus, but lack the infectious nucleic acid. These capsids are natural products of FMDV infection, are antigenically similar to virions, and are as immunogenic as infectious virus in animals (Grubman *et al.*, 1985; Rowlands *et al.*, 1974; Rweyemamu *et al.*, 1979). The empty viral capsids can be produced in various expression systems and then delivered to the animal. Alternatively, the DNA encoding the capsid-coding region and the $3C^{pro}$ required for capsid polypeptide processing can be delivered to the animal via DNA or viral vectors and the capsids synthesized in the animal. This latter approach has a potential advantage as compared with delivery of preformed empty capsids to the animal as the synthesis of the immunogen in the animal should induce both antibody as well as cell-mediated immune responses.

Li *et al.* (2008) used a silkworm–baculovirus expression system to produce FMDV Asia-1 empty capsids and vaccinated cattle with the hemolymph from infected silkworms. Four of the five animals were protected from homologous virus challenge. One potential limitation in the use of empty capsids as vaccine candidates is that in the absence of virion RNA they are less thermostable than the natural virus particle and therefore may be less immunogenic (Curry *et al.*, 1997). Porta *et al.*

(2013) attempted to enhance stability of baculovirus-expressed FMDV A22 empty capsids and also reduce expression of the toxic $3C^{pro}$. The mutated capsids were more stable than the WT capsids to both heat and acid and 3C expression and catalytic activity was reduced. Two of the four cattle vaccinated twice with WT empty capsids and an oil adjuvant and three of the four animals inoculated with mutant capsids were protected from challenge with homologous virulent virus (Porta *et al.*, 2013).

Other investigators have used viral vectors, including poxvirus, pseudorabies virus, and replication-defective human adenovirus (Ad5), as delivery vehicles (Grubman and Baxt, 2004; Zhang *et al.*, 2011). Thus far, the most efficacious viral-vectored delivery vehicle is the Ad5 system. The Ad5-FMDV A24 (Ad5-A24) vector constructed by Grubman and colleagues (Moraes *et al.*, 2001) is protective, after one inoculation, as early as 7 days postvaccination in both swine (Moraes *et al.*, 2002) and cattle (Grubman *et al.*, 2010; Pacheco *et al.*, 2005). More recent studies with second-generation vectors containing the NS protein 2B coding region demonstrated enhanced efficacy in challenge studies in swine (Pena *et al.*, 2008) and cattle (Moraes *et al.*, 2011). Furthermore, by changing the route and sites of inoculation the protective dose could be significantly reduced (Grubman *et al.*, 2012b). The US Department of Agriculture (USDA) in collaboration with the US Department of Homeland Security and GenVec Inc. have produced this vaccine on the US mainland in BSL2 facilities and tested it in cattle following the requirements of the Center for Veterinary Biologics of the Animal Plant and Health Inspection Service, USDA, which included safety testing of the vaccine in cattle at three sites on the US mainland. In June 2012 this vaccine was granted a conditional license for inclusion in the US National Veterinary Vaccine Stockpile for use in cattle in the United States in the event of an emergency situation.

Live-attenuated vaccines

A number of reviews have described early attempts to develop live-attenuated FMD vaccines (Bachrach, 1968; Brooksby, 1982; Mason and Grubman, 2009). These vaccines are economically cost effective to produce, should cause only mild or no disease, and theoretically can induce both adaptive and cell-mediated immune responses. Live-attenuated FMD viruses were developed by passage of WT virus in nonpermissive hosts including mice, rabbits, and embryonated eggs until their virulence for cattle was attenuated. However, although this approach has been successful in the development of very effective vaccines against yellow fever and polio, it has not been successful against FMD. Field studies in various countries demonstrated that although the attenuated strains could induce a degree of protection in a particular species it was often virulent in other susceptible species. In addition, there is concern that attenuated viruses created in this manner can revert to virulence.

More recently, scientists have used reverse genetics to mutate selected portions of the viral genome. McKenna *et al.* (1995) removed a portion of the region of VP1 required for binding to cells. This virus did not induce disease in inoculated swine or cattle and protected cattle from challenge with virulent FMDV. In another approach Piccone *et al.* (1995a) constructed a serotype A virus lacking the entire L^{pro} coding region, leaderless virus. Although this virus was infectious in BHK-21 cells, it grew to lower titers in primary cells, was attenuated in both swine and cattle, and induced a significant neutralizing antibody response (Chinsangaram *et al.*, 1998; Mason *et al.*, 1997). However, upon challenge animals vaccinated with this virus developed delayed and reduced disease signs as compared with naïve challenged animals. Similarly, a chimeric leaderless virus with a capsid from serotype O in a type A background was avirulent in cattle, but caused limited clinical disease in swine (Almeida *et al.*, 1998). Although, as already discussed (see Section Virulence Factors) L^{pro} is an important virulence factor it is clear that other regions of the viral genome are also involved in pathogenesis. Infection of cells with a virus with mutations in a conserved domain of L^{pro}, SAP domain (see Section Virulence Factors), does not result in cleavage of NF-κB (SAP virus). This virus was attenuated in swine, but induced a significant neutralizing antibody response (Diaz-San Segundo *et al.*, 2012). Furthermore, swine vaccinated with SAP virus were protected from challenge with the virulent parental virus as early as 2 days postvaccination.

New marked inactivated virus vaccines

Although live-attenuated FMD vaccines have thus far not been successful, a number of groups have tested these viruses as potentially safer DIVA inactivated vaccine candidates. Chinsangaram *et al.* (1998) showed that swine vaccinated with an oil-adjuvanted inactivated leaderless A12 virus or inactivated WT A12 virus induced very significant neutralizing antibody responses and protected the animals from homologous virus challenge. Utilizing the leaderless virus platform Uddowla *et al.* (2012) constructed an A24 leaderless virus with two negative markers. This virus was avirulent in cattle and swine and was not transmitted to naïve animals. In addition, an ELISA targeted to the negative markers was developed that successfully differentiated infected animals from vaccinated animals. Furthermore, cattle vaccinated with the oil-adjuvanted inactivated A24 leaderless negative marker virus developed an FMDV-specific neutralizing antibody response and were protected from clinical disease when challenged 21 dpv.

Fowler *et al.* (2011) observed that a negative marker inactivated vaccine could address the concern about differentiating infected animals from vaccinated animals. They isolated a virus, after passage of an Iranian vaccine strain in cell culture, lacking a 13 amino acid portion of the G–H loop of VP1 and developed an ELISA that could distinguish animals vaccinated with this immunogen from infected animals. Vaccinated cattle were protected from homologous WT virus infection.

Antivirals/Biotherapeutics

Inactivated and Ad5-FMD vaccines can only induce complete protective immunity by 7 days postvaccination (Golde *et al.*, 2005; Moraes *et al.*, 2002). Thus, before 7 days vaccinated animals exposed to virulent FMDV are still susceptible to the disease. As FMDV replicates and spreads very rapidly it is important, especially in an outbreak in an FMD-free country, to

quickly limit its dissemination. Ideally, a biotherapeutic agent in combination with a marked FMD vaccine could induce both rapid nonspecific protection and specific long-term vaccine-induced protection (Grubman, 2003).

As already discussed, type I and III IFNs are one of the first lines of host defense against viral infection and can inhibit FMDV replication in cell culture (Ahl and Rump, 1976; Chinsangaram *et al.*, 2001; Díaz-San Segundo *et al.*, 2011). On the basis of these findings and the clinical use of type I IFN in the treatment of various diseases including hepatitis C or B, Chinsangaram *et al.* (2003) constructed Ad5 vectors containing the gene for porcine IFN-α (poIFN-α). Swine inoculated with this vector and challenged 1 day later with virulent FMDV serotype A24 were clinically protected. Subsequently, this group demonstrated that protection could last for 3–5 days (Moraes *et al.*, 2003) and that swine challenged with FMDV O1 Manisa or Asia-1 1 day postinoculation were also protected, and that protection was induced by Ad5-poIFNβ treatment as well (Dias *et al.*, 2011). However, cattle treated with Ad5 containing bovine IFN-α were not completely protected, but developed delayed and less severe disease as compared with naïve challenged animals (Wu *et al.*, 2003).

More recently, Diaz-San Segundo *et al.* (Díaz-San Segundo *et al.*, 2011) constructed Ad5 vectors containing boIFN-λ (type III IFN) and demonstrated it has anti-FMDV activity in cell culture. After inoculation of cattle this vector induced upregulation of ISGs in the upper respiratory tract, which is the initial site of FMDV infection. Cattle administered Ad5-boIFNλ and challenged 1 day later with either FMDV A24 or O1 Manisa had significantly delayed and reduced severity of disease (Perez-Martin *et al.*, 2012).

It has also been demonstrated that type II IFN (IFN-γ) has antiviral activity against FMDV in cell culture (Moraes *et al.*, 2007; Zhang *et al.*, 2002). Using an Ad5-poIFNγ construct Moraes *et al.* (2007) showed that a combination of Ad5 vectors delivering both type I and type II poIFNs could protect swine from challenge 1 day later at lower doses than either alone. More recently, it was shown that poly ICLC, a synthetic dsRNA mimic and a potent inducer of IFN, could protect swine when challenged 1 day later with FMDV (Dias *et al.*, 2012).

In cell culture studies investigators have examined a number of antiviral compounds targeted to specific viral proteins including L^{pro} (Kleina and Grubman, 1992) and 3D (Rai *et al.*, 2013). In addition, antisense and RNA interference technologies (Chen *et al.*, 2004; de los Santos *et al.*, 2005; Fajardo *et al.*, 2012; Rosas *et al.*, 2003; Vagnozzi *et al.*, 2007) have been shown to block virus replication in cell culture. However, these technologies have not yet been tested in naturally susceptible animals.

Concluding Remarks

A wealth of new information has been obtained on FMDV at the molecular level, including many of the functions of the viral-encoded proteins, the interaction of the virus with the host, the pathogenesis of the disease, and the effect of infection on the host immune response. This information and the tools of reverse genetics and immunology have allowed us to develop new approaches to more rapidly detect and potentially better control this disease. New diagnostic assays, some of which can be used pen-side, should result in the rapid detection of disease. Likewise, new serological assays may allow a more rigorous differentiation of infected animals from vaccinated animals. A better understanding of the immunogens necessary to induce protection has resulted in the development of novel vaccine candidates that do not require high-containment facilities for production and allow for unequivocal DIVA assays. The demonstration that biotherapeutic approaches, such as the delivery of IFN genes, can rapidly induce protection before vaccine-induced immunity has opened additional possibilities of disease control. Nevertheless, the recent outbreaks of FMDV in a number of developed countries and the continued presence of FMD in many developing countries demonstrate the difficulty in controlling this disease.

Unlike rinderpest, which was the first eradicated animal disease, FMDV is antigenically diverse and infects many animal species including wild animals making it a much more difficult disease to control. FMD is still widespread in many developing countries, which do not have the infrastructure or the resources to effectively control the disease. Various international organizations including the FAO and OIE as well as regional organizations and developed countries have attempted to enhance aspects of disease control in developing countries. Most recently, the FAO and OIE have sponsored Global FMD Conferences in Paraguay in 2009 and in Bangkok in 2012. The outcome of these conferences has been the development and adoption by FAO and OIE of a multistep approach termed 'The Progressive Control Pathway (PCP)' to systematically help control FMD in countries in which it is enzootic. This approach requires both the affected countries and FMD-free countries, with knowledge and resources, to work together to increase the level of control so that countries will be able to gain OIE recognition as FMD free with or without vaccination (Sumption *et al.*, 2012).

It is clear that in a globalized world with an increasing population the need for more food including animal products is critical. Thus, the control of FMD is not only a problem for veterinary services and the livestock sector of the economy, but also has direct consequences on human health. It is, therefore, imperative for governments as well as private organizations to work together to continue to develop a more comprehensive understanding of FMD and to allocate sufficient funds to use this information to control and limit disease spread in all countries. Undoubtedly, if this type of global effort is not undertaken and sustained, all countries will suffer because of the continued presence of FMD.

Glossary

Antibiotic resistance A form of drug resistance in which certain microorganisms could survive after exposure to one or more antibiotic treatment.

Foodborne illness Any disease resulting from the consumption of food contaminated by pathogens, viruses, parasites, or toxins.

Prebiotics Nondigestible food ingredients that stimulate the growth or activity of bacteria (probiotics) in the digestive system and eventually benefit the host.

Probiotics Live bacteria that could have health benefits on the host.

Withdrawal periods Time required after administration of antibiotics in agricultural animals needed to ensure that antibiotic residues in meat, egg, or milk products is below the determined maximum residue limit.

Zoonotic pathogen Pathogenic bacteria that could cause an infectious disease that is transmitted between species from animals other than humans to humans, or from humans to other animals.

Introduction

Antibiotics are antimicrobial compounds that can inhibit and even destroy bacterial and fungal growth. Some compounds, such as aminoglycosides and penicillins, are isolated from living organisms, whereas others, such as oxazolidinones, quinolones, and sulfonamides, are produced by chemical synthesis. Accordingly, antibiotics can be classified based on their origin as natural origin, semisynthetic origin, or synthetic origin. Most of the common antibiotics used today are semisynthetic modifications of a variety of natural compounds. These antibiotics are used in both human medicine and animal agriculture to reduce incidences of diseases. They are usually administered by injection or orally via feed and water.

Antibiotics used for growth promotion in livestock and poultry not only allow the growth of healthier and more productive farm animals through improved weight gain and feed conversion efficiency, but they are also effective against animal diseases (Dibner and Richards, 2005). However, low-dose or specific employment of antibiotic as growth promoters that may involve bacterial antibiotic resistance and the replacement of these antibiotics with some natural products are under pressure.

Antibiotics widely administered in preharvest farm animals also help to reduce foodborne pathogens and prevent foodborne illness, which causes high morbidity and mortality rates worldwide. Currently, broad-spectrum antibiotics are commonly employed as feed additives for the preslaughter inhibition of foodborne pathogens. Owing to difficulties in determining specific agents targeting specific pathogen at the farm animal level, antibiotics have been shown to lower foodborne illness, and thus reduce morbidity and mortality, in humans (Callaway *et al.*, 2003). Other nonantibiotic antimicrobials are also used in foodborne pathogen prevention. These strategies include vaccination and the use of bacteriocins, bacteriophages, enzymes, probiotics, prebiotics, and organic acids.

As an essential strategy for controlling animal diseases, antibiotics have been employed in agricultural farming for therapeutic purposes. Multiple antibiotics have been approved for use against livestock diseases, including respiratory disease, enteric disease, and mastitis (Radostits *et al.*, 2007), as well as necrotic enteritis, chronic respiratory diseases, gangrenous dermatitis, fowl cholera, and avian influenza commonly seen in poultry (Pattison, 2008), as will be elaborated in this article.

Based on Page and Gautier's most recent study, commonly used classes of antibiotics in farm animals all over the world are summarized in **Table 1** (Page and Gautier, 2012).

Although the employment of antimicrobial agents has multiple significant benefits in animal agriculture, the appropriate use of these agents, including how to select the right ones, how to administrate them, and how to assess their risks, is a highly complex issue and continues to be a challenge for most growers and farmers. Knowledge and understanding of the common infectious diseases in multiple farm animals and guidelines for antimicrobial use in animal and animal products are crucial (Radostits *et al.*, 2007).

Some important topics addressed in this article include the patterns of antimicrobial use, preharvest and postharvest, therapeutic and subtherapeutic, nutritional, and for treatment. In addition, alternative antimicrobials and their appropriate employment in farm animals will also be discussed.

Antibiotics Used as Growth Promoters

Since the 1950s, antibiotics have been used as growth promoters in agricultural animal production in the United States, Australia, and several European countries (Dibner and Richards, 2005). Generally, 'growth promoter' refers to products that help to grow an animal faster for the same unit amount of feed consumed in a given period of time. Several researchers have shown that low-concentration (usually 2.5–50 mg kg^{-1}) addition of antibiotics to animal feed results in an accelerated growth rate and improved feed conversion efficiency in agricultural animals such as cattle, pigs, sheep, and poultry (Amy *et al.*, 2007). The improvement in average growth rate was estimated to be between 4% and 8%, and feed utilization was improved from 2% to 5% in 1994 (Ewing and Cole, 1999); a majority of recent studies have shown larger

 doi:10.1016/B978-0-444-52512-3.00187-X

Table 1 The most commonly employed antibiotics in farm animals worldwide

Country	*Year*	*Livestock*	*Poultry*
Australia	2006	Macrolides, penicillins, sulphonamides, and tetracyclines	–
Belgium	2009	Colistin, macrolides, penicillins, and tetracyclines	Macrolides and penicillins
Canada	2008	Lincosamides, macrolides, penicillins, and tetracyclines	–
Denmark	2010	Caphalosporin, macrolides, penicillins, penicillin-aminoglycoside, pleuromutilins, and tetracyclines	Macrolides, penicillins, and tetracyclines
Finland	2009	Aminoglycosides, beta-lactams, cloxacillin, fluoroquinolones, penicillin, and tetracyclines for all terrestrial species	
France	2010	Macrolides, penicillins, polymyxins, and tetracyclines	Penicillins, polymyxins, and tetracyclines
Germany	2005	Beta-lactams, sulphonamides, and tetracyclines for all species	
Japan	2004	Aminoglycosides, cephalosporins, macrolides, penicillins, sulphonamides, and tetracyclines	Aminoglycosides, macrolides, and tetracyclines
Kenya	2004	Aminoglycosides and penicillins for all farm species	
Netherlands	2009	Aminoglycosides, cephalosporins, colistin, neomycin, penicillins, penicillin-aminoglycoside, and tetracyclines	Colistin, fluoroquinolones, neomycin, penicillins, and tetracyclines
New Zealand	2009	Aminoglycosides, cephalosporins, macrolides, penicillins, penicillins sulphonamides, and tetracyclines	Bacitracin
Norway	2010	Aminoglycosides, penicillins, and sulphonamides for all terrestrial species	
South Africa	2004	Macrolides, penicillins, sulphonamides, and tetracyclines for food-producing species	
Sweden	2010	Macrolides, penicillins, pleuromutilins, and tetracyclines	Penicillins
Switzerland	2005	Aminoglycosides, penicillins, polymyxins, sulphonamides, and tetracyclines	Aminoglycosides, penicillins, sulphonamides, and tetracyclines
USA	2010	Macrolides, penicillins, sulphonamides, and tetracyclines for food-producing species	
UK	2010	Penicillins and tetracyclines for food-producing species	

benefits, up to 10% gain in both weight and feed conversion efficiency (JETACAR, 1999).

The exact mechanisms of growth promotion by antibiotics are still speculative. But, based on recent *in vivo* animal experiments, the antibactericidal effect of antibiotics is the most likely explanation for growth promotion. Antibiotics may help concentrate nutrients by reducing the amount of several intestinal bacteria that are able to divert nutrition away from an animal's body. In addition, antibiotics could also inhibit release of toxins in the gut by intestinal bacteria. Antimicrobial growth promoters could also help increase the availability and absorption of nutrients and energy by maintaining the composition of gut microflora, thus thinning the barrier in small intestine and at the same time assisting the digestion of grain-based high-energy diets.

Current Use of Antibiotic Growth Promoters

In the United States, beta-lactam antibiotics, especially penicillins and lincosamides, as well as macrolides, especially erythromycin and tetracyclines, are commonly used as growth promoters in pigs (Peter and John, 2004). Multiple other antimicrobial compounds are also used in US swine production to stimulate growth. These include arsenical compounds, bacitracin, flavophospholipol, pleuromutilins, quinoxalines, and virginiamycin (Peter and John, 2004). In Australia, similar antibiotics are employed in animal agriculture. Such growth promoters include arsenical compounds, flavophospholipol, macrolides (especially kitasamycin and tylosin), olaquindox, and streptogramin (especially virginiamycin) (JETACAR, 1999). Compared to the United States and Australia, the application of antibiotics in growth promotion in the European countries is relatively limited. In pig production, avilamycin, flavophospholipol, and ionophores, especially monensin and salinomycin, are among the few approved growth promoters in use in Europe (Angulo, 2004).

In the cattle industry, major antibiotics including flavophospholipol, monensin, and virginiamycin are commonly used as growth promoters in the United States (Peter and John, 2004). Owing to the high energy requirements of cattle, growth promoters may play an important role by stimulating muscle formation and improving milk productivity (Peter and John, 2004). However, the use of growth promoters can have several side effects in cattle. The most common harmful effect is lactic acidosis, which both impairs milk production and debilitates cattle. To counteract this side effect and maintain a balance between benefit and harm, administration of lasalocid and monensin are probably the safest and most effective antibiotic growth promoters due to their activity in inhibiting most of the lactate-producing bacterial species without harming the major lactate fermenters. Australian cattle farmers also employ flavophopholipol, lasalocid, and monensin (JETACAR, 1999). Other cattle growth promoters used in Australia include narasin, oleandomycin, and salinomycin. The use of glycopeptide avoparcin was no longer permitted after 2000. In the European Union, the same types of ionophores – monensin and salinomycin – are used in cattle. However, the use of

pristinamicin and quinupristin has been banned since 2000 (Dibner and Richards, 2005).

For the poultry meat and egg industries, specific growth promoters such as flavophospholipol and virginiamycin are employed in the United States (Peter and John, 2004). In Australia, poultry producers use arsenical compounds, flavophospholipol, bacitracin, and virginiamycin (JETACAR, 1999). Growth promoters are not allowed to be used in layer farms in Australia. In Europe, major growth promoters used in the poultry industry include avilamycin, avoparcin, bacitracin, and virginiamycin. According to several recent studies, a 10 mg per kg dose of avoparcin is able to improve feed conversion efficiency by 2.96%, increase the growth rate of meat chickens by 2.37%, and increase 1.33 net cents per kg liveweight; 17.6 mg per kg dose of virginiamycin, similarly, is able to increase these three values by 3.48%, 3.19%, and 1.48%, respectively (Mehdi *et al.*, 2011).

The Future of Antibiotic Growth Promoters

In 2000, the World Health Organization (WHO) recommended several global principles, including rapidly phasing out all antibiotic growth promoters from agricultural animal production, specifically those that are used in the treatment of human diseases (World Health Organization, 2000). Four years later, WHO also recommended for assessment of risk and surveillance of antibiotic growth promoters used in agricultural animals and the pattern of antimicrobial resistance in various animal and human bacterial pathogens (World Health Organization, 2004).

Though the relationship between application of antibiotics in farm animal production and the trend of antimicrobial resistance in human bacterial pathogens is still under debate, the idea of antibiotic-free animal production is based on an emotional level instead of a legislative level. In fact, from the point of view of many consumers, the use of antibiotics as growth promoters has negative effects on public health, and a certain percentage of consumers want to reduce or control the use of antibiotics in food animals, regardless of their practical advantages. The use of antibiotics as growth promoters is being curtailed under consumer pressure. The replacement of these antibiotics/antimicrobials with some consumer-friendly and natural organic bioactive components is a potential area of research interest worldwide.

The Potential Alternatives to Antibiotics for Growth Promotion

In light of the declining demand for antibiotic growth promoters, more and more research has been focused on developing alternatives to growth stimulation and improving feed utilization and efficiency. Since the benefits of growth promotion may result from the alteration of gut microflora, alternatives to antibiotic growth promoters may be required to improve animal intestinal gut flora through natural and organic bioactive and functional feed supplements. Therefore, research interest has concentrated on following the five approaches: in-feed enzymes, probiotics, prebiotics, organic acids, bioactive phytochemicals, and competitive exclusion of pathogens by-products being administered via water or feed. So far, none have been proved to replace the use of antibiotics in growth stimulation thoroughly and successfully, and thus further research is needed. The possibilities of using these potential alternatives to synthetic antibiotics are explored below.

In-feed enzymes

Feed enzymes have been employed extensively in both livestock and poultry feed for more than 15 years, especially in wheat- or barley-based diets (Choct, 2002). In-feed enzymes are usually produced by fermentation of fungi and bacteria, after which these are used to stimulate growth as additives in animal feeds. Several studies have investigated the effectiveness of in-feed enzymes as a substitute for antibiotic growth promoters for improving nutrient absorption and digestibility, gaining body weight, and animal performance. Based on recent studies, it was demonstrated that in-feed enzymes often have activities in promoting digestion of feed components that are normally poorly digested or totally undigested in agricultural animals (Hedemann *et al.*, 2009). The mechanism by which in-feed enzymes promote digestion of feed components is believed to involve the breakdown of those hard-to-digest chemical components in the grains and meals such as nonstarch polysaccharides, especially arabinoxylans and beta-glucans, phytates, and proteins (Gerard *et al.*, 2011). Added routinely to the feed of livestock and poultry, these enzymes are efficient at maximizing feed conversion efficiency, and more importantly they have no or very few side effects. As a consequence, numerous researchers are now focusing on improving the quality of existing enzymes, intending to broaden the range of feed ingredients in which they could be used as alternative growth promoters.

Competitive exclusion products

Owing to the increasing concerns about the role of chemical antibiotics in bacterial resistance in both agricultural animals and humans, and following Darwin's competitive exclusion principle, many researchers are seeking biological alternatives to replace antibiotic growth promoters with competitive exclusion products. Competitive exclusion products are usually processed from and composed of various species of undefined or partially defined bacteria isolated from the gastrointestinal tracts of agricultural animals. Products such as Broilact™, Avigard™, and Preempt™ are often administered to newborn animals, especially poultry, and have shown their effectiveness in animal growth promotion, gut health maintenance, and even the control of pathogenic infection (Alaeldein, 2013). Several studies have found that a significant improvement of animal feed conversion ratio using Avigard treatment results from the reduction in feed intake and also the prevention of pathogenic colonization such as *Salmonella* and *Campylobacter* from the gut (Gerard *et al.*, 2011). At the same time, multiple competitive exclusion products can also help reduce diarrhea and mortality levels, but the mechanisms remain unclear.

Probiotics

Similar to competitive exclusion products, probiotics are defined as directly fed mono- or mixed cultures of living microorganisms that can compete with undesired microbes

and benefit the host by improving the properties of the indigenous microbiota (Fuller, 1992). Available probiotics can be divided into two main categories. One category is colonizing species such as *Lactobacillus, Lactococci,* and *Enterococcus*; the other is free-flowing noncolonizing species, which include both *Bacillus* and *Saccharomyces cerevisiae*. These beneficial microbes are able to ameliorate the overall health of animal by improving the gut microbial balance; however, their exact mechanism is still under investigation. One major hypothesis for their actions could involve their influence on intestinal metabolic activities, including the improvement of bacteriocins, propionic acid, and vitamin B12 production, and increasing the villous length and nutrient absorption (Christina *et al.*, 2009). Other possible mechanisms include competitive exclusion of pathogenic microorganisms and their immunostimulatory activities.

Probiotics are also effective in helping boost weight gain and feed conversion rates in newborn animals. However, several questions about the active strains, the maximum dosage, the effective delivery system, and the potential risks remain unanswered and need to be further investigated. One more potential danger of using live probiotics refers to their antibiotic resistance. A report from the Scientific Committee on Animal Nutrition (2001) concerning the safety of probiotic products found that *Lactobacillus plantarum* and *Pediococcus acidilactici* were tetracycline-resistant. As a consequence, the use of probiotics could possibly put the whole food chain and the environment at risk. Moreover, the permanent establishment of probiotics in animal gastrointestinal tracts is difficult. Several studies have indicated that gut microflora are active and efficient in preventing new organisms from colonizing and becoming established (Jonsson and Conway, 1992). Finally, the high cost and high dosage of administration required for probiotics for growth promotion might also be a serious drawback to their widespread application in animal agriculture.

Prebiotics

Prebiotics are nondigestible feed ingredients that are able to provide selective stimulatory effects on both the growth and metabolic activity of certain gut microflora, including the probiotics mentioned above. Their effects are based on the nature of the compound, but essentially they could exert the same or similar actions as probiotics. Unlike probiotics, which are foreign microorganisms introduced into the gut competing with colonic communities which have already become established, the chief advantage of employing prebiotics in improving gut function is that their target bacteria are already commensal with the large intestine (Macfarlane *et al.*, 2008). However, prebiotics cannot be effective if the targeted beneficial bacteria are not in the gut due to, for example, antibiotic therapy or intestinal diseases. One potential area of future research would be examining the combined effect of both probiotics and prebiotics, known as 'synbiotics,' for the replacement of antibiotic growth promotants (Louise, 2009).
